$$s^2(FE) = \frac{cflgd^3}{2000}$$

$$s^2(FE) = 8.09$$

where $c = 3.8 \times 10^6$, $f = 0.5$, $l = \sqrt{0.01 \div 0.64} = 0.12$, $g = 0.25$, and $d = 0.64$ cm (0.25 in.). A variance of this magnitude would indicate a very low precision on the estimate of grade.

The point of the previous examples is to emphasize that in order to sample low grade gold deposits with a reasonable degree of precision, the samples should be reduced to 1.7

mm (10 mesh) or smaller prior to making any split. In this example as well as the preceding, an ore grade has been assumed. In the initial stage of exploration of a property, the grade distribution is unknown. However, as exploration proceeds, there will be some indication of what range of grades are to be expected in a given deposit.

ASSAYING

The traditional technique of assaying for gold and silver is the fire assay, and the method is still considered to be the reference standard of the industry. Atomic absorption spectrometry methods have been developed in recent years, most of which produce good results when proper care is exercised in sample digestion and preparation of standards. Some companies rely on atomic absorption for routine assays due to the somewhat lower cost, particularly in areas where there is sufficient experience to confirm the reliability of the method. It is considered good practice, however, to fire assay up to 25% of any sample group to maintain control.

As in all sampling programs, it is necessary to establish a check sampling procedure by which a certain percentage, usually about 10% of the sample pulps, are renumbered and resubmitted to the same laboratory. Samples should also be sent to outside laboratories for check analyses. It should be mentioned that there will usually be a wide variation in check assays on an individual sample basis. The mean for specific lots, however, should check fairly closely.

At an early stage of the evaluation program of a precious metal deposit, if cyanidation [either for heap leaching or conventional countercurrent-decantation (CCD) circuit methods] appears to be a potential recovery method, bottle roll tests often are carried out on drill samples. These tests give an idea of cyanide extractability of the precious metals in the ore.

STATISTICAL CONSIDERATIONS

Precious metal deposits are usually characterized by high variability. Shown on Table 1 are the coefficients of variation of approximately equivalent size samples for various types of precious metal deposits. By comparison, the coefficients of variation for various other deposit types are shown in Table 2. The high variability of the precious metal deposits is readily apparent in comparison with those other deposits.

Most precious metal deposits have a lognormal frequency distribution, examples of which are shown in Fig. 1. When a deposit has this type of distribution, the calculation of the lognormal mean and variance often gives more accurate results than a straight arithmetic average. The tables prepared by Sichel may be utilized for the calculation of lognormal

Fig. 1a. Histogram of disseminated silver sample values, stock-work silver deposit, Rochester District, Nevada.

means. The methodology of the calculations is detailed in Section 4 of this chapter.

The use of lognormal averages also provides a means of accounting for the erratic high values that usually occur in any set of assay data from a precious metal deposit. Another method which has been applied in some mines is to cut all high values to a value equal to the mean plus twice the standard deviation of the original data set. This method often has a tendency to undervalue the grade of many deposits.

The critical aspect of the grade estimate of a precious metal deposit is the realization that the grade represents a point on a probability distribution, not an absolute value. If the sampling and assaying has been carried out correctly and without bias, the grade estimate should be reasonably precise, but the high natural variability of this type of deposit will always inject a high degree of uncertainty in most grade

estimates. This consideration is of prime importance in determining the economic viability of a project.

RESERVE CALCULATION

The calculation of an ore reserve should be much more than a mathematical exercise. Whether a manual method of calculation such as cross sections, polygons, or grade-thickness contours is employed, or computerized block models are constructed, the estimation procedure must take into account the geological and mineralogical characteristics of the deposit. There have been many cases in the recent history of the mining industry where these factors have been ignored, often with disastrous results.

There is sometimes a tendency, particularly when computerized evaluation techniques are utilized, to treat the data strictly as a set of numbers, without keeping in mind that the numbers refer to a volume of rock in the ground. Also, the large uncertainties involved in generating the assay data base tend to be forgotten once the data is in the computer. When the computer models are constructed, geological boundaries such as structural features, lithologic contacts, and mineralizational zones must be respected.

For these reasons, the preparation of an ore reserve should be a cooperative effort between geologists, mining engineers, and systems personnel. Metallurgical input should also be incorporated at as early a stage as possible. The critical aspect of an ore reserve is not the ore in the ground,

but the amount of final product that can be profitably extracted. If the final metal production is significantly less than anticipated, the entire exercise of reserve estimation has been in vain.

3.4.2 Reserve Estimation of Uranium Deposits

HARRY M. PARKER

INTRODUCTION

Uranium deposits are nearly universally characterized by erratically distributed mineralization that is commingled with barren material. Because of this commingling and the relatively high costs of beneficiation of the ores to produce a salable product (twice to three times the cost per ton of treatment of copper ores), uranium mines tend to be small operations that allow the maximum practicable segregation of ore from waste.

The very close-spaced sampling, on which decisions to select ore from waste are made, is generally done just prior to or during mining, and hence this information is not available for making reserve estimates. Instead, wider-spaced exploration or development sample data must be used to predict the tonnage of ore and grade of ore within an area of the deposit or even within the deposit taken as a whole. Precise blocking of ore and waste, that is possible in making reserve estimates for the more massive and/or continuous deposits of iron ore, coal, or many base metal ores, is not possible for uranium. This factor is recognized in the planning of uranium operations, and sufficient stockpiles and/or exposed mineralized zone (typically three to six months mill feed) are maintained so that fluctuations between predicted reserves and actual production are smoothed out.

Because of the erratic character of the mineralization, it is often difficult to determine geologic controls on ore/waste contacts or even the outlines of mineralized areas with a degree of certainty sufficient to increase the accuracy of reserve estimates. Because of this difficulty in locating precise ore/waste boundaries, reserve methods in common use are either deterministic (polygons) or statistical (probabilistic). Both methods have been successfully applied in the evaluation of reserves for a large number of prospects and operating mines.

The appropriate use of these methods is described in subsequent sections. However, before considering the methodology, it must be emphasized that the accuracy of any reserve estimate depends ultimately upon the accuracy of the samples used. In most sandstone-hosted uranium deposits and in some "hard-rock" deposits, the assay is not a chemical or other direct analysis, but a radiometric equivalent based on counts of gamma radiation received per time interval at a detector. Proper probe calibration is important to guarantee that a systematic bias is not introduced in the "assays."

It is also important to recognize that most of the gamma radiation is emitted by daughter-product elements. The uranium and/or its daughter products may be locally selectively leached and/or redeposited leading to "disequilibrium" and more or less gamma radiation arriving at the detector than there would be expected for a given grade of uranium if this migration had not occurred. Investigation of disequilibrium and local correction for it is critically important to produce unbiased reserve estimates. This is particularly true in the case of roll-front deposits where uranium and its daughter products have been successively oxidized, leached, reduced, and redeposited. Disequilibrium correction factors of between 0.5 and 2 are not uncommon in these environments.

METHODS OF ASSAYING

An extended discussion of various assaying techniques is beyond the scope of this chapter. In general two methods of assaying are in common use, X-ray fluorescence (XRF) and natural gamma logging.

X-Ray Fluorescence (Core or Chip Samples)

This method has proven to be a rapid inexpensive replacement of wet chemical analyses. The sample is irradiated by X-rays that cause elements within the sample to give off or fluoresce X-rays in turn. Characteristic spectra are emitted for each element, and the number of emitted X-rays at characteristic wave lengths are proportional to the amount of the element present. A spectrometer is used to measure the count rate of emitted radiation at various wave lengths. Because elements other than uranium will often emit X-rays of nearly the same wave lengths as those emitted by uranium, adjustments termed matrix corrections are often made by computer to give a refined estimate of the amount of uranium present. A helpful discussion of the subject is given in Levinson (1974).

Natural Gamma Logging (Within Drill Holes)

Gamma rays are emitted as uranium radioactively decays to lead. As given in Dodd, et al., (1967), uranium itself has a rather long (4.5×10^9 years) half-life compared to some of its less stable daughter products such as radium (1622 years), radon (3.82 days), lead-214 (26.8 min), and bismuth-214 (19.7 min). Of these isotopes the latter two are the significant gamma ray emitters. The implications of this are explained by Dodd, et al., (1967):

"If uranium is in secular equilibrium with its gamma-emitting daughters, and if there is an insignificant contribution of gamma rays from other sources, then the concentration of uranium in the rocks immediately surrounding a bore hole can be determined from a gross-count gamma-ray log with high sensitivity and practical accuracy. Because of the geochemical characteristics of the various radionuclides, these conditions are seldom, if ever completely fulfilled. Fortunately, for many economically valuable concentrations of uranium these conditions are sufficiently met, or data may be obtained to supply adequate corrections, to determine the thickness and mean equivalent grade of the mineralized zone from the gross gamma-ray log and by calculation, to closely approximate the grade of incremental layers within the zone."

Scott, et al., (1961), have shown that the grade-thickness product is proportional to the area under the peaks of anomalies (plotted in counts per second) on radiometric logs. The counts per second recorded on the log are a biased estimate of the counts per second emitted by the rock surrounding the drill hole. Casing, if present, water, and mud in the hole absorb some of the radiation before it can reach the detector, and hence the reading is generally increased by a factor often termed the *water correction factor*. The correction for casing is sometimes made separately (S.P. Morzenti, personal communication). Also, when the detector receives an X-ray photon, a pulse of electric current is generated causing a "count" to register. While this "registration" is occurring, other incoming photons cannot be counted. The time it takes this to occur, usually only a few

microseconds, is termed the *dead time* of the detector. The following formula generally is used to estimate the counts per second actually emitted by the rock:

$$N = \frac{(\text{water correction factor})(\text{measured counts per sec})}{1 - (\text{measured counts per sec})(\text{dead time in sec})} \quad (1)$$

Thus if the water correction factor were 1.07 and the dead time were 5.5×10^{-6} sec, an observed count rate of 6000 would be adjusted to 6639 counts per sec.

Prior to the widespread use of computers, the grade and thickness of ore for each peak were calculated by hand, as described by Linton (1963). Figs. 1 and 2, reproduced from Stoll (1972), illustrate the technique. Basically the thickness is taken to be the distance between the upper and lower half-peak amplitudes measured to the nearest $\frac{1}{2}$ ft (15 cm). As shown in Figs. 1 and 2, the accumulation (grade \times thickness or GT) in % U_3O_8 in feet is found to be:

$$GT = K \left(\sum_{i=1}^n N_i + 1.38 (E_1 + E_2) \right) \quad (2)$$

Here the factor K permits conversion of counts per second into grade-thickness units. It is determined by calibrating the probe in a hole drilled through a "test pit" containing known grade. Details of the procedure are provided in Scott, et al., (1961), and Dodd, et al., (1967).

The grade (measured in percent U_3O_8 in the United States and percent uranium in much of the rest of the world) is obtained by dividing GT by the estimated thickness in feet. This is so even though the number of measurements between the half-peak amplitude marks E_1 and E_2 is $2T$. If a grade were to be desired for a $\frac{1}{2}$ ft (15 cm) zone, ignoring the ends of the anomaly, then:

$$G(0.5) = KN$$

$$G = 2KN \quad (3)$$

Scott (1963) developed a more sophisticated method to predict the grade using a computer. As shown in Fig. 3, a mineralized zone is made up of a series of layers, each of which has anomalous gamma radiation, and which superimpose to give the observed anomaly. Scott hypothesized that a series of $\frac{1}{2}$ ft (15 cm) layers could be found to which synthetic grades could be assigned that would reproduce the anomaly. These synthetic grades could then be used in reserve estimation. He next calculated the amplitude of an anomaly for a $\frac{1}{2}$ ft layer at various distances from the center:

i	Distance from Center, (ft)	Relative Amplitude	W_i
$i-3$	-1.5	2%	0.01
$i-2$	-1.0	8%	0.04
$i-1$	-0.5	40%	0.20
i	0.0	100%	0.50
$i+1$	0.5	40%	0.20
$i+2$	1.0	8%	0.04
$i+3$	1.5	2%	0.01

The amplitude at position i on a log may be thought to be made of contributions from adjacent positions using the stated weight factor W_i . To obtain the grade at i , as a first approximation the grades are assigned to all positions using the formula:

$$g_i = 2KN_i \quad (4)$$

Grades for the three positions above and below the logged zone are assigned $g_i = 0$.

Fig. 2. Gamma-ray log interpretation worksheet (Stoll, 1972).

The grades g_i are assigned to G_i , the observed composite anomaly. Then the synthetic anomaly grades are assigned for all i except the three positions on either end of the anomaly:

$$G'_i = \sum_{i=i+3}^{i=i+3} W_i g_i \quad (5)$$

For the first time $g_i = g_i^0$. The difference between G_i and G'_i is found and added to the g_i as a correction:

$$g_i(\text{new}) = g_i + (G_i - G'_i) \quad (6)$$

For the first time $g_i = g_i^0$. Then the process is repeated with a new set of G'_i being computed from the $g_i(\text{new})$. The differences are taken again and a new set of $g_i(\text{new})$ created, etc. Should a $g_i(\text{new})$ be found negative, it is set to zero.

When the maximum difference is found to be less than significant, typically 0.0025% U_3O_8 , the synthetic grades g_i

(new) are accepted and the process is terminated. Generally convergence is obtained within 10 to 15 iterations. It is wise to set a maximum of 25 to prevent endless looping for exceptional cases.

Programs using this algorithm have been developed by the Grand Junction Office of the Department of Energy (formerly the Energy Research and Development Administration, ERDA, and before that the Atomic Energy Commission, AEC). The programs have been referred to variously as GAMLOG, MDDAT, or MDAT and have been used by many companies in the US mining industry.

S.P. Morzenti of Exxon Minerals (personal communication) has commented that some probes in current use give different shaped anomalies from those studied by Scott, and therefore different weighing factors should be used. The reader should consult the probe manufacturer for advice.

The successful use of gamma logs to predict the uranium content is dependent on the assumptions presented in the papers referenced being met. Key among these is the assumption of horizontal stratification of the mineralization, that is met in most undeformed sandstone deposits and a

Fig. 3. Complex uranium ore zone and equivalent hypothetical $\frac{1}{2}$ ft (15 cm) thick layers with associated gamma-ray anomalies (Scott, 1963).

constant K -factor that is independent of grade. Robert Enwall of Rocky Mountain Energy Company (personal communication) has found that significant overestimation of the grade occurred when these assumptions were made for a low-grade (less than 0.05% U_3O_8) deposit with mineralization contained along steeply dipping fractures.

Other Techniques

Several logging techniques employing neutron fission are beginning to come into commercial use. These techniques, described by Czubek (1972), involve pulsed generation of neutrons from a source in the drill hole and measurement of the epithermal neutron time distribution (prompt fission neutron method, PFN) or the delayed neutron distribution from fast neutron fission or uranium-238 or thermal neutron fission of uranium-235. These techniques are not dependent on equilibrium between uranium and its daughter products and offer promise of rapid, accurate direct measurement of the uranium content of ores.

More recently, as is described in *Engineering & Mining Journal* (1980), a probe has been developed that measures only the gamma radiation from protactinium-234. Protactinium is the first daughter product of uranium and has a half-life of only 26 days. Hence it will be in equilibrium with the uranium from which it is produced. This tool has been used in routine exploration and drilling programs and is considered operational and reliable (Ken Weissenburger, CONOCO Inc., personal communication). The method has the advantage over the neutron fission methods in that the latter use a "hot" source that requires special handling and

could be lost in the process of logging with environmental consequences.

DISEQUILIBRIUM CORRECTIONS

The discrepancy between radiometric gamma log equivalent assays and chemical or XRF assays is often loosely termed *disequilibrium*. As shown by Hansink (1976) if uranium is leached from the tail zone of a roll front, less soluble daughter products such as radium, radon, lead, and bismuth that emit 98% of the gamma rays remain, and the grade, if not corrected, will be overestimated. Conversely in the protore zone ahead of the nose of the roll front, uranium is being or has been redeposited without the time necessary to build up concentrations of gamma-ray-emitting daughter products.

In fact the discrepancy between gamma logs and assays of core may be due in various degrees to the following factors:

- 1) Geometry of mineralization other than horizontal.
- 2) Use of linear K factor when nonlinear should apply.
- 3) Instrument drift, inaccurate water correction factor, dead time correction, etc.
- 4) Volume-variance relationship of sample volumes (core volumes are smaller than volumes swept by the probe). The ratio of chemical to gamma log value is sometimes called the sampling factor.
- 5) Inaccuracies or systematic biases in collection of cores such as poor core recovery or sample preparation.
- 6) Inaccurate match between cores and gamma logs.
- 7) Presence of anomalous potassium-40 in feldspars, micas, and clay minerals, or thorium in hard-rock deposits.

8) True disequilibrium between uranium and its daughter products. This includes migration of uranium or its daughter products (such as radon which may move into highly porous or fractured zones).

Measurement of disequilibrium has been described by Rosholt, et al., (1965), Santos (1975), Killeen and Carmichael (1976), and Ostrihansky (1976). As indicated previously simple study of radiometric vs. chemical analyses of the same sample usually is not enough. Disequilibrium may be overshadowed by discrepancies due to other factors previously listed. A good rule (Sam Smyth, personal communication) is to have at least 10% of the drill holes be cored to establish geographic and hopefully geologic control on the discrepancies.

Correction for discrepancies has been found to be relatively straightforward for deposits where remobilization has not occurred. Fig. 4 shows a linear regression correction which was made for a stratabound uranophane deposit. This should be contrasted to Fig. 5 that is taken from a roll-front deposit in Wyoming. Here lognormal regression has been used to make the correction. The procedure for doing this is as follows:

- 1) Plot both chemical (chem) and radiometric (gamma) assays separately on lognormal probability paper. For each distribution find a constant C to add to the assays Z such that $Z + C$ is lognormal (plots as a straight line, see Fig. 6). Details of the procedure are described in Rendu (1978).
- 2) Let:

$$Y_{\text{chem}} = \ln (Z_{\text{chem}} + C_{\text{chem}}) \quad (7a)$$

$$Y_{\text{gamma}} = \ln (Z_{\text{gamma}} + C_{\text{gamma}}) \quad (7b)$$

Perform a linear regression of Y_{chem} on Y_{gamma} and find a predicting equation:

$$Y_{\text{chem}}^* = A (Y_{\text{gamma}}) + B \quad (8)$$

- 3) Because Y_{chem}^* , the expected value of Y_{chem} given Y_{gamma} , is not the logarithm of the mean (expected value of $(Z_{\text{chem}} + C_{\text{chem}})$ given $(Z_{\text{gamma}} + C_{\text{gamma}})$ that is desired, a final correction is required:

Fig. 4. Scatterplot of core analyses vs. gamma log and linear regression line.

Fig. 5. Scatterplot of core vs. gamma log analyses and nonlinear regression line obtained by lognormal regression.

- Cumulative Frequency for Assays
- Cumulative Frequency for Assays + 0.015

Fig. 6. Plot of uranium assays on lognormal probability paper.

$$(Z_{\text{chem}} + C_{\text{chem}})^*$$

$$= \exp \left[A (Y_{\text{gamma}}) + B + \frac{s^2 (1 - \rho^2)}{2} \right] \quad (9)$$

where s^2 is the variance of Y_{chem} and ρ is the correlation coefficient between Y_{chem} and Y_{gamma} .

Finally, the estimated chemical value is

$$Z_{\text{chem}} = (Z_{\text{gamma}} + C_{\text{gamma}})^* \exp \left[B + \frac{s^2 (1 - \rho^2)}{2} \right] - C_{\text{chem}} \quad (10)$$

Dagbert and David (1979) have devised a more complicated method involving hermite polynomials that may be used when the distributions of the assays are not lognormal or three-parameter lognormal. Bryan and Roghani (1982) estimate the disequilibrium factor, chemical/radiometric, by co-kriging principal components formed from 12 geologic variables. These predicted components are then used in a regression equation to predict the disequilibrium factor. As the disequilibrium factor may also be dependent on grade (as shown in Fig. 5), it is suggested that the gamma log value be added to geologic variables if this procedure is to be used. Marbeau and Marechal (1980) provide an illusory smoothing technique using co-kriging on composites; unfortunately when the scatter is as great as is shown in Fig. 5, no method will provide a very accurate correction. In the face of this, and making the assumption that uranium leached

from the tails of rolls is redeposited in the protore zone ahead of the noses, some companies do not attempt to correct for disequilibrium in roll-front environments. Reserve estimates based on these assumptions may or may not be biased globally, but most certainly will be locally, particularly where the deposit is above the water table. Here oxidation and leaching have generally occurred. As a consequence, only the daughter products remain.

Other companies, such as Exxon's Highland, WY, operation, calculate disequilibrium factors for geologic environments, such as roll near wing, wing, far wing, etc., and monitor the actual disequilibrium encountered during production. (S.P. Morzenti, personal communication).

RESERVE ESTIMATION USING DETERMINISTIC METHODS

Polygonal Approach

As stated in the introduction, most uranium mines are small-scale, highly selective operations. Typically the ore stringers in a roll-front deposit may be less than 1.5 m (5 ft) thick and 4.6 m (15 ft) wide perpendicular to strike (Sandefur and Grant, 1976). As indicated by these authors, drilling on 3-m (10-ft) centers would be required to outline the ore bodies. The cost of this sampling would be prohibitively expensive.

Sandefur and Grant show that the reserves may be accurately determined by weighting the grade-thickness product of ore in each hole by its polygonal area of influence. The following steps are followed:

1) Ore intercept definition. A minimum minable thickness is defined, typically 0.7 to 1 m (2 to 3 ft). Very often 15 cm (0.5 ft) may be added to the top and bottom at grade

or zero grade to represent dilution. A minimum grade is defined that the intercept must meet to be accepted. Reserves are often categorized according to the intercept criteria, e.g., "2 ft (0.7 m) of 0.04," "3 ft (0.9 m) of 0.06," etc.

The assays, whether corrected radiometric equivalent or chemical, are examined to determine the intercepts for each hole. This process is often computerized. The intercepts are generally chosen without regard to a common datum or bench level, as mining typically follows the ore/waste contacts. The thickness and grade-thickness product of each intercept are noted. Sometimes the intercept will be tagged with a level or geologic horizon indicator. This permits tabulation of reserves by geographic position or geologic horizon within the deposit.

2) A polygonal area of influence is computed for each hole. Polygonal boundaries are perpendicular bisectors of lines connecting adjacent holes. (The area of influence of isolated holes is often restricted.) Fig. 7 shows a typical map.

3) The reserves in an area of a deposit are simply calculated:

$$\text{Accumulation (metal content)} = Q^* = K_Q \sum_{i=1}^n A_i q_i \quad (11)$$

$$\text{Tonnage} = T^* = K_T \sum_{i=1}^n A_i t_i \quad (12)$$

$$\text{Grade} = G^* = \frac{\sum_{i=1}^n A_i q_i}{\sum_{i=1}^n A_i t_i} \quad (13)$$

Fig. 7. Polygonal areas of influence for a stratabound uranium deposit.

where A_i is the area of polygon of influence for hole i ; t_i is the thickness of ore intercept(s) for hole i ; q_i is the grade-thickness product of ore intercept(s) for hole i ; K_Q is the conversion factor to obtain kilograms, pounds, etc., of uranium; and K_T is the density or tonnage factor.

It is common practice in many mines to drill higher grade or accumulation areas on a tighter spacing. Because these intercepts often have limited areal extent, it is appropriate to weight these holes less in a reserve estimate, as is done by the polygonal method. A lower weighting of closer holes also reflects the possible spatial correlation and duplication of information provided.

Fig. 7 shows that it is possible, particularly if a specific geologic horizon is considered, to have non-ore holes commingled with ore holes. Given the remarks referenced earlier by Sandefur and Grant, the polygons must be thought of as tools to assign areas of influence (weights) to the assays to obtain an unbiased estimate of reserves, and *not* tools to block out ore on a local basis for mine planning. During mining, ore will be found to occur in non-ore polygons and vice versa.

Table 1, reproduced from Sandefur and Grant (1976), shows the variation in polygonal reserves for various hole spacings. There is little change once the number of holes in ore becomes statistically large [at the 61-m (200-ft) spacing]. As explained subsequently, geostatistics may be used to define the appropriate hole spacing.

Journel and Huijbregts (1978, p.464) and Parker (1979) have shown polygonal estimates to be biased in many mines

because of internal dilution toward overestimation of grade. Where the cutoff grade is above the mean, the tonnage is also overestimated. Where the cutoff grade is below the mean, the tonnage is underestimated. This is because the grade and tonnage estimates are based on a declustered (area of influence weighted) distribution of sample volumes, and the assumption is implicitly made that selection of ore from waste will be made on similar sized volumes. In many (other than uranium) mines this does not occur. The selection is based on estimates of larger volumes, up to several thousand tons in extent, that are comprised of many sample-sized volumes, some of ore and some of waste grade material, leading to the internal dilution mentioned previously.

In highly selective uranium operations the difference between polygonal estimates and recovered reserves has *not* been found to be a problem. This is because of the degree of selectivity. Probing of ore in the pit on spacings as close as 0.6 m (2 ft), mining with as small as 0.8 m³ (1 cu yd) backhoes, and scanning of truck loads, typically containing 23 to 45 t (25 to 50 st), all contribute to accurate selection of ore from waste using selective mining units of similar volume to that detected by a gamma logging probe.

Cross-Sectional Approach

The cross-sectional approach has been used to outline hard-rock uranium deposits, such as those found in the Athabasca region of Saskatchewan or Northern Territory of Australia. The same erratic character of grade is seen in vertical section as in the horizontal direction for the roll-

Table 1. Polygonal Ore Reserves Based on Various Drill Hole Spacings

front deposits. Ore intersections are projected into blocks surrounding drill holes. Because ore is localized in veins or high-grade pods, accurate assessment of reserves is difficult. The geostatistical approaches outlined in the next section are only beginning to be implemented and offer hope of improvement in the accuracy of reserve estimates.

Inverse-Distance Approach

With the advent of computers it was recognized by Weiss and O'Brian (1971) that locally weighted averages of bench composites could provide better estimates than polygons of the reserves on a local basis. This is because the use of all samples that are spatially correlated with the block should provide a better estimate than using the closest sample. Invoking the theory that closer samples should be better predictors than ones further away, the inverse-distance (often inverse distance squared) method of assigning weights to samples was tried. Unfortunately in most cases computer users did not understand the highly selective nature of uranium mining and the limited extent of the ore bodies. They mistakenly performed inverse-distance weighting on ore and waste composites alike. This resulted in a markedly lower estimate of overall grade than would be obtainable with polygons and geologically unrealistically smoothed ore/waste contacts. As a result, the uranium industry has largely rejected use of this method.

Were inverse-distance weighting applied to grade-thickness and thickness of ore intercepts to estimate the tonnages and accumulation of ore in mine planning units, the method would be useful in providing both unbiased estimates of overall reserves and better and unbiased estimates of local reserves than that provided by polygonal estimators. However, as shown in the next section, more accurate geostatistical methods have been developed that perform the same function.

Remark

Much has been said throughout this paper of the high degree of selectivity of uranium operations and the need to be cognizant of this in developing reserve estimates. This is true for most but *not all* operations in existence. There are in existence and were until the recent decline in uranium sales price several contemplated low-grade deposits at which large-scale less-selective mining methods are used or were envisaged. Reserve estimation for these deposits have thus far been mainly treated using geostatistics. As explained in the next section, a deterministic approach to reserve estimation for these deposits is not recommended.

RESERVE ESTIMATION USING STATISTICAL METHODS

Because of the erratic distribution of the grade and tonnage of uranium ore bodies within a deposit, statistical methods that make inferences about a population (the ore bodies) from samples are useful, and as shown by Sandefur and Grant (1980) may provide a superior accuracy of prediction. There is a trade-off, however. The methods and their applicability must be thoroughly understood to achieve success. A detailed explanation of the theory would be of necessity too lengthy to be provided here. The reader is referred to the section of this chapter by J.M. Rendu for an introduction. Excellent texts on basic statistics as applied to geological and mining problems have been written by Koch and Link (1970) and Davis (1973). Textbooks on geostatistics by David (1977), Journel and Huijbregts (1978), Rendu (1978), and Clark (1980) are also helpful. Discussion papers on uranium reserve estimation using geostatistics have been

written by Parker and Chavez (1979), David and Dagbert (1980), and Marbeau and Marechal (1980). The selection of the appropriate method depends on the density of data, geology, and selectivity of mining method. Described in the following are methods that have been shown to work and for which published case studies are available.

Geostatistical Setting

As mentioned previously, uranium deposits tend to be comprised of distinct ore bodies within a zone of weak or even barren mineralization (see Fig. 7). Thus two populations exist that can be referred to as the barren and the mineralized population. As shown in Fig. 8 taken from Parker, et al. (1979), the grade of the mineralized population is often approximately lognormally distributed (and by adjustment of the barren/mineralized cutoff can sometimes be made to be lognormally distributed). Sandefur and Grant (1980) have also shown that the grade-thickness product of ore intercepts may also be lognormally distributed.

Where the deposit is thick and comprised of many interlayered ore bodies, that may happen if the cutoff criteria are low, nearly every hole may have a positive grade-thickness product, as shown in Fig. 9. On the other hand, if the grade-thickness product is being computed over a single stratigraphic horizon, with high cutoff criteria, many holes that intersect only the barren or weakly mineralized population may occur, as indicated in Fig. 8. In these cases it can be advantageous to estimate the area underlain by ore by coding each hole with an indicator 1 if ore bearing and 0 if barren, and kriging (refer to the section by J.M. Rendu) this variable to estimate the proportion of the area underlain by ore.

Obtaining variograms for uranium deposits is a difficult task given the strong local proportional effect (Fig. 10) between mean and standard deviation within pods of mineralization and the erratic distribution of grade and change in directions of anisotropy throughout the deposit. The proportional effect may be handled by calculating relative variograms (variograms that are scaled by dividing by a function of the mean $f(m)$). Very often $f(m) = m^2$ has been found to apply and can be theoretically proven in the lognormal case. A full explanation is found in Journel and Huijbregts (1978, pp.187-191, 250-251). Alternatively, variograms on the logarithms may be calculated (Fig. 11), that may be converted to a relative variogram provided the underlying distribution is multivariate lognormal using the following formula:

$$\gamma_{\text{rel}} = \exp [C_{\log}] [1 - \exp (-\gamma_{\log}(h))] \quad (14)$$

where C_{\log} is the sill of the variogram of logarithms.

Knudsen and Kim (1979) found that by calculating the variogram parallel and perpendicular to the roll-front axes, significant anisotropy in the spatial variability (ratio of the ranges of 2.5) could be observed. Parker, et al., (1980), coded the strike direction of the roll fronts within the deposit and locally oriented the variogram search cone (Fig. 12) to obtain the along- and across-strike variograms shown in Fig. 13. If the roll-front orientation varies even more than indicated by exploration drilling, the successfulness of this technique maybe limited.

One characteristic of nearly all variograms is a relatively short range [often less than 50 m (163 ft)] and a high nugget effect. This implies that accurate local reserve estimates will be difficult to obtain without close-spaced drilling. It also means that selective mining units that are *significantly* larger

Fig. 8a. Histogram of mineralized population.

Fig. 8b. Histogram of barren population.

than sample-sized volumes will have markedly different grade-tonnage curves from that of samples (polygonal estimates).

Reserve Estimation with Sparse Data

This section applies to the early exploration stage, when for example 50 or less holes are available, of which some may be barren and some mineralized, and the spacing is beyond the typical range of influence of a variogram. In this case estimation of mean ore grade-thickness by taking the arithmetic mean of positive grade-thickness intercepts can provide a misleading estimate of the mean grade-thickness of ore. As demonstrated by Koch and Link (1970), when samples are drawn from a skewed distribution, the maximum likelihood is that the arithmetic mean of samples will be below the deposit mean. This is because much of the uranium content is contained in rare rich zones that will most likely not be intersected in the first pass of drilling. For example, in one project on which the author monitored the reserves, the mean grade-thickness rose by 20% over the course of going from 50 to 400 holes. On the other hand, occasionally the first pass may intersect one of the rich pods in which case the arithmetic average of the data would be biased high, and extreme caution is warranted in making reserve estimates.

The grade-thickness is often approximately lognormally distributed. This can be checked by plotting the available data on log probability paper. In this case the Sichel t estimator may be used to find an unbiased estimate of the mean. A description of the technique is given in Sichel (1966) and in David (1977). This method uses the logarithms of the sample data to estimate the mean. It must be used with discretion since it only yields an unbiased estimate when the underlying distribution is lognormal and when the data are distant enough from one another to allow assumption of their independence. This is difficult to verify with a small amount of data. The Sichel method also provides an estimate of confidence limits on the estimate. These are heavily dependent on inferences made about the distribution and calculation of the variance and statistical independence of samples, and must be weighed with caution.

The distribution of thickness of ore-bearing holes tends to be less skewed and is best estimated using the arithmetic average of the data. Computation of tonnage obviously depends on extrapolation around and interpolation between ore-bearing holes. In the absence of sufficient information upon which to base a mine plan, classifying this tonnage as reserves is inappropriate. Using geologic judgment to outline favorable areas and *provided the drilling density is uniform*, the area underlain by ore may be taken to be equivalent to the proportion of ore holes multiplied by the total area judged to be favorable.

Given the estimated average grade-thickness is q^* , the estimated average thickness of ore-bearing holes is t^* , and the proportion of area underlain by ore is estimated to be p^* , the resources may be estimated to be:

$$\text{Accumulation (metal content)} = Q^* = K_Q A p^* q^* \quad (15)$$

$$\text{Tonnage} = T^*P = K_T A p^* t^* \quad (16)$$

$$\text{Grade} = G^* = q^*/t^* \quad (17)$$

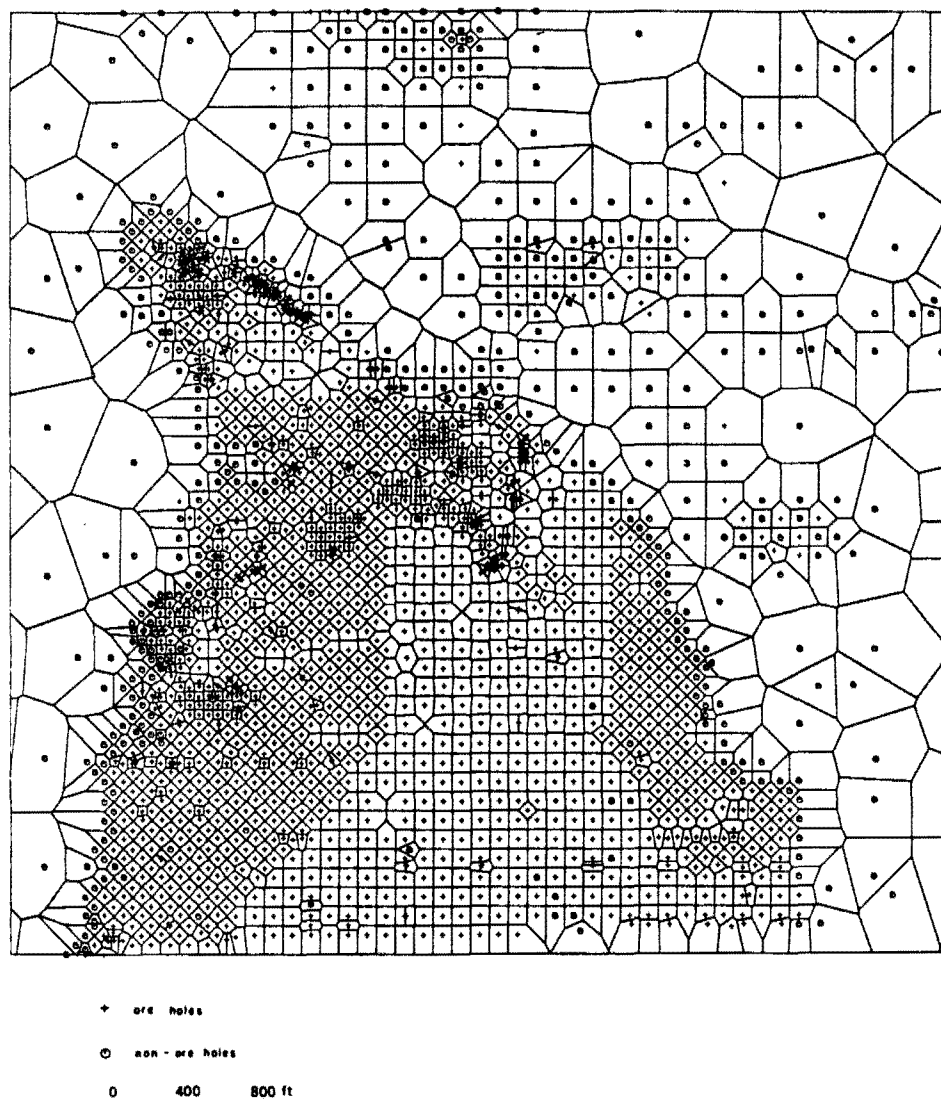

Fig. 9. Ore and barren holes penetrating several mineralized horizons using a low cutoff grade (Sandefur and Grant, 1976).

where A is the total area (ore bearing and barren); K_o is the conversion factor to obtain kilograms, pounds, etc., of uranium; and K_T is the density or tonnage factor.

This approach was found to work well for the author in drilling out several township sized areas near Crownpoint, NM. The approach also provided unbiased estimates for a simulated deposit based on a mined out area in the Grants, NM, mineral belt. In general, as the drill hole spacing is reduced by infill drilling, so is the favorable area A . This is offset by an increase in p^* and the area underlain by ore remains relatively constant. Confidence limits on the estimates may be calculated, as is described in the next section.

Reserve Estimation For Very Selectively Mined Deposits

This section describes techniques for reserve estimation of deposits for which the frequency distribution of selective mining units is essentially the same as that of the samples. The procedures must be separately applied for each set of cutoff criteria. In setting these criteria, the method of mining must be taken into account (e.g., lift height for excavator,

ore loss due to overlying waste removal, etc.). The following steps should be followed:

- 1) Correct the radiometric assays for disequilibrium and other factors and obtain the thickness and grade times thickness product for ore-grade intercepts. These intercepts can be calculated on a diluted basis using the comments made previously in the section on polygonal estimators as guides. Intercepts may be restricted to geologic horizons or slices as desired. As an example of the latter, composites were made every 0.9 m (3 ft) for a Wyoming roll-front deposit. The thickness and grade-thickness product of ore-grade composites were accumulated every 2.7 m (9 ft). These resultant accumulated thickness and grade-thickness variables were used for kriging.

- 2) Plot the thickness and grade-thickness variables and define areas of interest for reserve estimation. Compute the histogram of thickness and grade-thickness variables within this area. If there are more than 15% barren (zero thickness) intercepts, it is suggested an indicator variable be defined as 1 if the thickness is nonzero and 0 if the thickness is zero.

- 3) Make a plot of thickness and grade-thickness on cu-

Fig. 10. Scatterplot of mean vs. variance for grade-thickness for various levels from a Wyoming roll-front deposit.

mulative probability paper and log probability paper, respectively.

4) Make a proportional effect plot of mean vs. standard deviation for areas within the deposit. The definition of areas is made by inspection and using geologic judgment. In general, they should be as large, but as homogeneous, as possible. Typically 10 to 20 areas (or volumes) are defined within the area (volume) for which the reserves area is to be estimated. The areas should parallel the ore zones in their orientation.

5) Using the proportional effect relationship, compute composite relative variograms (see Journel and Huijbregts, 1978). The variograms should be oriented as necessary to follow geologic trends. Logarithmic variograms may be used and converted to relative variograms if the underlying distribution is shown to be lognormal.

6) Compute variograms on the indicator variable if it is

Fig. 11. Logarithmic variogram of a total grade thickness, distance between samples in feet (H), (Sandefur and Grant, 1980).

Fig. 12. Comparison of oriented and non-oriented variograms (Parker, et al., 1980).

to be used. If there are large differences in the proportion of ore intercepts locally, the indicator variograms should be computed locally. A composite relative indicator variogram should be calculated by dividing each indicator variogram by $(m)(1-m)$ where m is the mean of the indicator data in an area and compositing the resultant variograms.

7) Compute the correlation coefficients between thickness and grade-thickness product. In general, thickness and grade-thickness product will be correlated between 0.3 and 0.7.

8) Perform ordinary linear kriging for the grade-thickness product q^* , thickness t^* , and indicator p^* , if used. Kriging should be done using the relative variograms. Sizes of blocks kriged should be smaller than the areas used to compute proportional effects (i.e., the samples and block should be close enough together so that stationarity of the variogram may be assumed). Blocks need not be rectangular and may be irregular areas corresponding to mineralized trends.

9) Compute the estimation variances for the thickness, grade-thickness product, and indicator variable, if used. These are computed by multiplying the relative estimation variance by $f(m)$, where m is usually taken to be the estimate.

10) Compute the estimated metal content, tonnage, and grade for each block:

$$\text{Accumulation (metal content)} = Q_i^* = K_Q A_i p_i^* q_i^* \quad (21)$$

$$\text{Tonnage} = T_i^* = K_T A_i p_i^* t_i^* \quad (22)$$

Fig. 13a. Oriented variogram for grade-thickness (Parker, et al., 1980).

Fig. 13b. Oriented variogram for thickness (Parker, et al., 1980).

$$\text{Grade} = G_i = q_i^* / t_i^* \quad (23)$$

where A_i is the total area of the block; K_Q is the conversion factor to obtain kilograms, pounds, etc., of uranium; and K_T is the density or tonnage factor. If the indicator is not used, set $p^* = 1$.

11) Compute the *relative* estimation variance for accumulation, tonnage, and grade as follows:

$$\frac{\sigma_{Q_i}^2}{Q_i^2} \approx \frac{\sigma_{p_i}^2}{p_i^2} + \frac{\sigma_{q_i}^2}{q_i^2} \quad (24)$$

$$\frac{\sigma_{T_i}^2}{T_i^2} \approx \frac{\sigma_{p_i}^2}{p_i^2} + \frac{\sigma_{t_i}^2}{t_i^2} \quad (25)$$

$$\frac{\sigma_{G_i}^2}{G_i^2} \approx \frac{\sigma_{q_i}^2}{q_i^2} + \frac{\sigma_{t_i}^2}{t_i^2} - 2 \rho_{qt} \frac{\sigma_{q_i} \sigma_{t_i}}{q_i t_i} \quad (26)$$

where $\sigma_{p_i}^2$ is the estimation variance (not relative estimation variance for the indicator), $\sigma_{q_i}^2$ is the estimation variance (not relative estimation variance for the accumulation), $\sigma_{t_i}^2$ is the estimation variance (not relative estimation variance for the thickness), and ρ_{qt} is the correlation coefficient between accumulation and thickness.

These formulas are standard applications for computing the variances for the product and quotient of random variables (see Journel and Huijbregts, 1978, pp. 424-426). In practice, p , q , and t are replaced by their estimates p^* , q^* , and t^* . The formulas assume that there is no correlation between indicator and grade-thickness or thickness. This is

because the indicator will be constant, equal to 1, when the grade-thickness and thickness are defined. If the indicator is not used, $\sigma^2_{p_i}$ is set to zero.

The term *relative* in this section and those that follow is not used in the same way as in determining the *relative* variogram. The estimation variances are always divided by m^2 , where m is the estimate, and not $f(m)$, except when $f(m) = m^2$ so that confidence limits may be calculated relative to the estimate.

12) The total reserve is found by accumulating the block values:

$$\text{Accumulation} = \sum_{i=1}^N Q_i \quad (27)$$

$$\text{Tonnage} = \sum_{i=1}^N T_i \quad (28)$$

$$\text{Grade} = \frac{\sum_{i=1}^N Q_i}{\sum_{i=1}^N T_i} \quad (29)$$

13) Provided the blocks are large enough to not share too much of the data used to make estimates, the errors of estimation may be considered independent. The *relative* estimation variances for the entire deposit will approximately be:

$$\frac{\sigma^2_{Q_{\text{Deposit}}}}{Q_{\text{Deposit}}^2} \approx \frac{\sum_{i=1}^N Q_i^2 \sigma_{Q_i}^2}{\sum_{i=1}^N Q_i^2} \quad (30)$$

$$\frac{\sigma^2_{T_{\text{Deposit}}}}{T_{\text{Deposit}}^2} \approx \frac{\sum_{i=1}^N T_i^2 \sigma_{T_i}^2}{\sum_{i=1}^N T_i^2} \quad (31)$$

$$\frac{\sigma^2_{G_{\text{Deposit}}}}{G_{\text{Deposit}}^2} \approx \frac{\sum_{i=1}^N T_i^2 \sigma_{G_i}^2}{\sum_{i=1}^N T_i^2} \quad (32)$$

14) Relative confidence limits may be put on quantity of metal, tonnage, grade, etc., by assuming the distribution of errors is normal. This assumption is reasonable if the relative standard deviation of the estimation errors is less than $\pm 25\%$. For example:

$$\begin{aligned} &\text{Relative} \\ &90\% \text{ Confidence} \\ &\text{Limits} \\ &= \pm 1.645 \sqrt{\text{relative estimation variance}} \quad (33) \end{aligned}$$

Thus if the relative estimation variance for tonnage were 0.01, the relative 90% confidence limits would be 0.1645; that is, with 90% confidence the true tonnage should be within $\pm 16\%$ of the estimated tonnage.

The confidence limits that can be attached to reserves based on various drill hole spacings can be estimated by applying these formulas to blocks or an aggregation of blocks. As an example, consider the estimation of thickness in a deposit with a variogram range of 60 m (200 ft), spherical variogram, no nugget effect, and relative sill equal to 0.50. A 450 \times 900-m (1500 \times 3000-ft) area is to be explored. Table 2 shows confidence limits estimated for various hole spacings.

From the table it can be seen that reducing the drill hole spacing down to the range of the variogram is effective in establishing tight confidence limits at the deposit (global) scale on the variable being estimated. Beyond this there is a severely diminished return in increased confidence per additional hole drilled. Drilling within the range of the variogram may be required to bring local reserve estimates to a required degree of precision, that may be restated as outlining the grade and tonnage of ore for short and intermediate range production planning and scheduling. It is important to note that geostatistics is capable of predicting the results established empirically by Sandefur and Grant (1976), without resorting to fill-in drilling.

In many geostatistics texts, for example, David (1978) and Journel and Huijbregts (1978, pp. 428-438), formulae are given for estimating the error in prediction for tonnage or metal content in the area of the surface underlain by ore. In this presentation the outline of the mineralized area that contains the ore bodies has been treated as a constant. This is because, although the geologist's or mining engineer's outline may not correspond to the actual outline, in the exploitation of the deposit mining will proceed to the outline (pit wall). The outline will not generally be altered for waste found at the time of mining to locally extend into the pit or ore found to extend beyond the walls.

A second problem with the formulae is that they assume a uniform drill hole spacing, that is usually not the case, and do not admit to the presence of waste within areas surrounded by ore holes, or ore within areas surrounded by waste holes. The indicator kriging approach, that takes both nonuniform hole spacing and the latter factors into account, is believed by the author to be a preferable approach to the problem.

It must also be recognized that this presentation ignores the case (for simplicity) when chemical data are presented in large numbers. Guarascio (1976) handled this by co-kriging. The error of estimation that is due to disequilibrium and other factors is also disregarded (for simplicity). If a downhole variogram of residuals (actual chemical value-corrected value) shows a short range and/or a high nugget effect the error due to local incorrect adjustment for disequilibrium may be neglected. If not, better corrections are needed, or more data enabling better corrections must be taken. Although maps showing plots of residuals can be helpful, for most deposits insufficient data are collected to

Table 2. Confidence Limits vs. Hole Spacings

Hole Spacing, meters (ft)	No. of Holes	$\pm 90\%$ Relative Confidence		
		Limits %	Increase in No. Holes	Decrease in Confidence Limits
125 (400)	37	18.7	N.A.	N.A.
90 (300)	57	12.9	25	5.9
60 (200)	128	5.9	71	7.0
30 (100)	512	0.9	384	5.0
15 (50)	2048	Nil	1536	0.9

allow for study of the horizontal regionalization of disequilibrium or its correction. Therefore assessment of the additional error due to disequilibrium in a reserve estimate is difficult, and statements as to the precision of reserve estimates should be treated with caution.

Similarly, there is no allowance for error in the computation of the density K_r in the formulas. For most deposits this is standard practice. If a variable density is suspected, it should be investigated and densities assigned spatially to rock units using lithologic logs.

Reserve Estimation for Less Selectively Mined Deposits

This section describes techniques for reserve estimation of deposits for which the frequency distribution of selective mining units has significantly (at least 10%) lower variance than that of samples or composites of samples.

Assessment of Grade-Tonnage Curves for Selective Mining Units: The first task is to establish the selective mining unit. This will normally be the volume surrounded by four blastholes, but may be as small as a truck load if scanners are used to classify the loads. In many cases computing the reserves for several selective mining unit sizes can be useful. The variance of selective mining unit grades will be inversely proportional to the volume (Parker 1979). Using a selective mining unit height as the composite length, the declustered frequency distribution within the mineralized portion of the deposit should be calculated. The *mineralized portion* should be that area in which the ore occurs. It should include barren areas that may be encountered during mining, but exclude barren areas around the fringes of mineralization that will probably not be included within the pit. Polygonal areas of influence should be used to weight (decluster) the composites in constructing the frequency distribution. If a polygon construction program is not available, the deposit may be divided into blocks. The number of composites in each block is noted and the weight assigned to a composite is the volume of the block divided by the number of composites. The mean and variance of the frequency distribution are computed.

Horizontal variograms are then made. If variograms of composite grades are erratic, logarithmic or relative variograms may have to be used. In this case these should be transformed to give an estimate of the average variogram of composites for the deposit. If necessary the sill of this transformed variogram should be rescaled to the variance of the frequency distribution, $\sigma^2_{\text{composites}}$.

The mean of the frequency distribution of selective mining units will be the same as the mean of the frequency distribution of samples, m . The variance of the selective mining units will be smaller:

$$\sigma^2_{smu} = \sigma^2_{\text{composites}} - \bar{\gamma}_{smu} \quad (34)$$

σ^2 composite is best estimated by the sill of the variogram. $\bar{\gamma}_{smu}$ can be calculated from graphs in Journel and Huijbregts (1978) or found by taking the average value of the variogram between points within the selective mining unit (usually 25 to 100 points).

There are a number of ways to adjust the frequency distribution of composites to obtain the frequency distribution of selective mining units. The two most common are the affine correction and the indirect lognormal correction (Journel and Huijbregts, 1978, pp. 468–471).

In the first instance (affine correction) the grades of the *distribution* of selective mining units are estimated by:

$$Z_{smu} = \frac{\sigma_{smu}}{\sigma_{\text{composites}}} (Z_{\text{composite}} - m) + m \quad (35)$$

To form the frequency distribution, the influence (tonnage) assigned to a Z_{smu} is the tonnage fraction assigned to the corresponding $Z_{\text{composite}}$. The tonnage above cutoff is found by multiplying the total tonnage of the deposit times the tonnage fraction above cutoff. The grade above cutoff is found by a tonnage fraction weighted average of the Z_{smu} above cutoff.

To use the second method (indirect lognormal), the distribution of composites should be verified as approximately lognormal. The assumption is made that the distribution of smu will be approximately lognormal. Under these assumptions the mean of the two distributions will be the same, m . The variance of the logarithms will be approximately:

$$\beta^2_{\text{composites}} = \ln \left(1 + \frac{\sigma^2_{\text{composites}}}{m^2} \right) \quad (35a)$$

$$\beta^2_{smu} = \ln \left(1 + \frac{\sigma^2_{smu}}{m^2} \right) \quad (35b)$$

Then the proportion of material above cutoff Z_c assuming strict lognormality will be:

$$P^c_{\text{composites}} = \phi \left[\frac{1}{\beta_{\text{composites}}} \ln \left(\frac{m}{Z_c} \right) - \frac{\beta_{\text{composites}}}{2} \right] \quad (36A)$$

$$P^c_{smu} = \phi \left[\frac{1}{\beta_{smu}} \ln \left(\frac{m}{Z_c} \right) - \frac{\beta_{smu}}{2} \right] \quad (36b)$$

where ϕ is the standard normal cumulative density function that is tabulated in introductory statistics texts.

The grade of material above cutoff, assuming strict lognormality, will be:

$$G^c_{\text{composites}} = \frac{m \phi \left[\frac{1}{\beta_{\text{composites}}} \ln \left(\frac{m}{Z_c} \right) + \frac{\beta_{\text{composites}}}{2} \right]}{P^c_{\text{composites}}} \quad (37a)$$

$$G^c_{smu} = \frac{m \phi \left[\frac{1}{\beta_{smu}} \ln \left(\frac{m}{Z_c} \right) + \frac{\beta_{smu}}{2} \right]}{P^c_{smu}} \quad (37b)$$

Then the frequency distribution for selective mining units may be found by:

$$p_{smu} = \frac{P^c_{smu}}{P^c_{\text{composites}}} p^c_{\text{composites}} \quad (38)$$

where p_{smu} is the estimated actual proportion of selective mining units above cutoff Z_c and $p^c_{\text{composites}}$ is the actual proportion of composites above cutoff. If p_{smu} is multiplied by the total tonnage in the deposit, the tonnage above cutoff may be estimated.

If the grade above cutoff g_{smu} is desired, the formula is:

$$g_{smu} = \frac{G_{smu}^c}{G_{composites}^c} g_{composites}^c$$

where $g_{composites}^c$ is the tonnage-weighted average of grades of composites above the cutoff.

Once the frequency distribution of selective mining units is obtained, the estimated recoverable metal content, tonnage, and grade from selective mining units above a given cutoff can be computed. An example of the application is given in Table 3. In this example the effect of selective mining unit height on recoverable reserves was investigated.

For this deposit the 3-m (10-ft) case was selected because the 1-m (3-ft) case was not deemed practical considering the high ore and waste production rate specified in the mine design criteria.

A comment is made that recoverable reserves computed using this method must be taken as rough global estimates. Often there is insufficient close-spaced drilling to accurately define the variogram, particularly the nugget effect, at spacings required to calculate $\bar{\gamma}_{smu}$. The assumption is made that selective mining units will be perfectly selected at the time of mining. Considering that blasthole probing and face and truck scanning, if properly corrected for local disequilibrium and other factors, can accurately predict the grade, further slight adjustment of the frequency distribution for grade control errors is usually not warranted.

In any case, the relative changes in recoverable reserves with change in selective mining unit volume may be assessed using this approach.

Assessment of Local Reserves: Local reserve estimation may be done by ordinary linear kriging if the estimation variances are not so high as to cause appreciable smoothing effects. This may be investigated by kriging a panel of sufficient size to be useful for mine planning with a typical configuration of data:

$$\text{Variance of kriging estimates} \approx \text{variance of panel grades} - \text{estimation variance} \quad (39)$$

For some deposits rich and poor zones can be delimited by geologic contacts. In these cases kriging should be restricted to the ore-bearing area. The selective mining unit/panel size may vary within the deposit.

For large-scale mining operations a panel may be larger than a selective mining unit (see Fig. 13). It is important to compare the variance of the kriged panel estimates to σ_{smu}^2 . If the difference is small (as a rule-of-thumb less than 20%),

the grade-tonnage curve and mine planning, based on kriged estimates, will be representative of the recoverable reserves. An adjustment for the additional sampling available and better selection possible at the time of mining can be made to the grade-tonnage curve of kriged estimates using either the affine or indirect lognormal method explained previously.

Unfortunately, except in operating mines with a wealth of blasthole and other development drilling data, there will be a large difference between the variance of the kriging estimates of panels and the variance of the selective mining units. This difference occurs because the data are widespaced and sample-panel correlation is small, leading to large estimation variances. In addition selective mining units are usually much smaller than panels (that may be used for mine planning), which further increases the discrepancy between the variance of kriged estimates and that of recoverable reserves.

In these cases what is desired is not the prediction of each selective mining unit's grade within the deposit or even within a panel. What is required is an estimate of the frequency distribution of the grades of selective mining units within a panel. Using the frequency distribution, the amount of waste, amount of ore-grade selective mining units, and grade of ore-grade selective mining units can be predicted for each panel.

Nonlinear geostatistical methods are used to make the predictions. These methods, though they have been tried on several deposits, have not been tested to the extent that linear kriging estimators have been tested. They nearly all depend on strong hypotheses of stationarity of the frequency distribution of grade from place to place within the deposit, and make inferences as to the shape of the distribution of selective mining units using the distribution of composite samples.

Lognormal Shortcut—The easiest method to apply is the lognormal shortcut method of David, et al. (1977). Although the method is described to apply to blastholes in a copper deposit, it has been adapted to prediction of selective mining units. It has been successfully used (S.P. Morzenti, Exxon Minerals, personal communication) in an operating mine, with the benefit of production data to correct variances and remove biases. The conditional distribution of selective mining unit grades within the panel is presumed to have a lognormal distribution with mean and variance:

$$\text{Mean} = \text{ordinary linear kriged estimate, } Z^* \quad (40)$$

$$\text{Variance} = \text{Kriging estimation variance} + \text{dispersion variance of selective units within a panel} \quad (41)$$

The dispersion variance of selective mining units within a panel is estimated to be:

$$\sigma_{smu/panel}^2 = \bar{\gamma}_{panel} - \bar{\gamma}_{smu} \quad (42)$$

Given the mean and variance of the lognormal distribution, the proportion of ore and grade of ore can be estimated using Eqs. 35b, 36b, and 37b.

Correct use of this technique relies heavily, especially where the cutoff grade is above the mean, on the assumption that the distribution of selective mining units will be lognormal and that the formula for the variance is correct. In deposits with strong proportional effects, Eqs. 41 and 42 should be evaluated using relative variograms and variances and then adjusted by multiplying by $f(Z^*)$. Usually $f(Z^*)$

Table 3. Effect of Selective Mining Unit Height on Recoverable Reserves*

	Selective Mining Heights			
	1 m (3.3 ft)	3 m (9.8 ft)	6 m (19.7 ft)	12 m (39.4 ft)
Contained Uranium	1.00	0.88	0.78	0.58
Tonnage	1.00	0.95	0.90	0.79
Grade	1.00	0.92	0.86	0.73

* 1-m height taken as base case and figures quoted are relative to it.

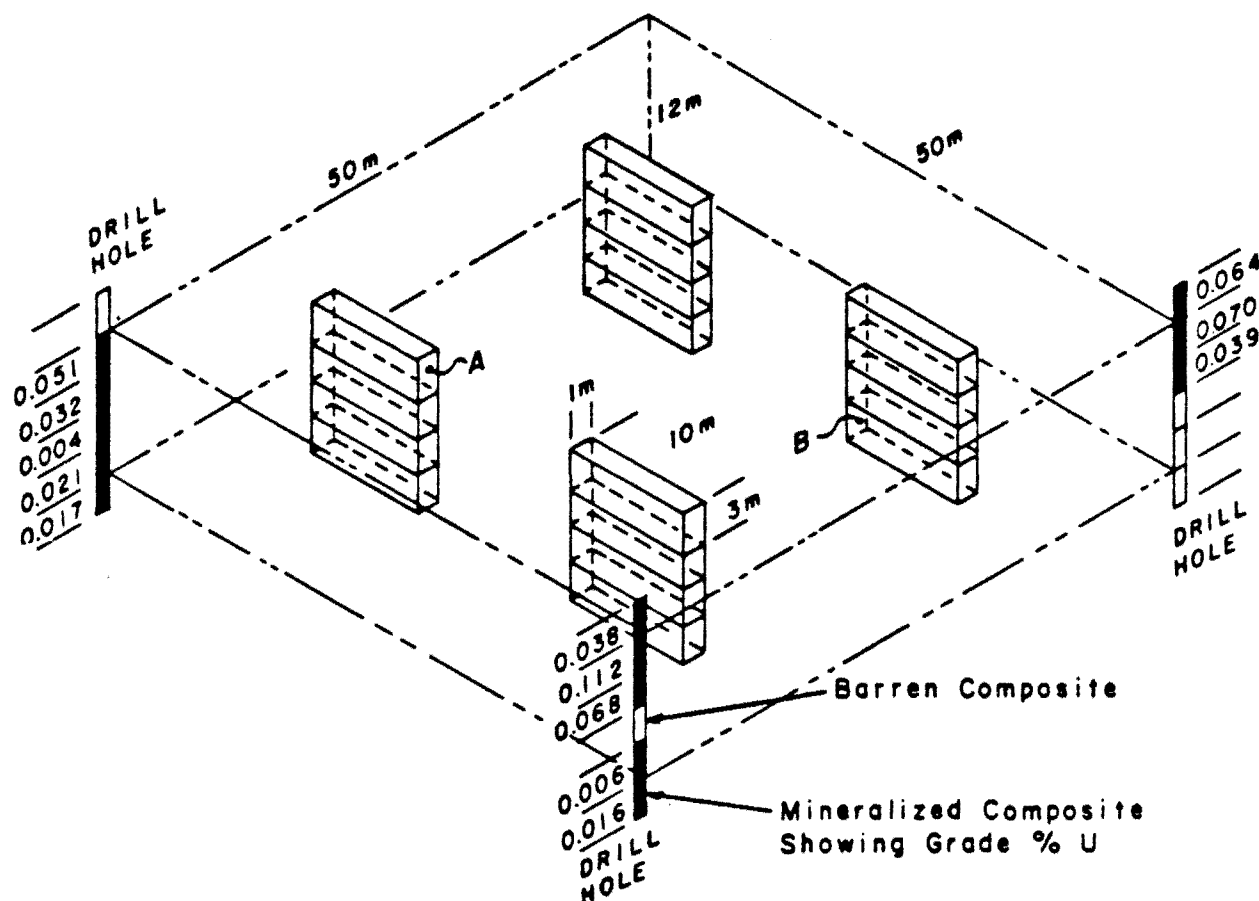

Fig. 14. Relative configuration of selective mining units, panel for mine planning, and drill holes (Parker, Journel, and Dixon, 1979). There are 1000 selective mining units in a panel, but only 16 of them distributed on 4 evenly spaced stacks are considered for the estimation of the minable reserves within the panel.

$= Z^{*2}$. In addition, the formula should be recognized to be an approximation of the more complex method described subsequently. The extent to which the assumption of lognormality and the approximation holds cannot be verified prior to mining. The author prefers the more complicated method to be described next that provides a more rigorous estimate of the conditional frequency distribution of grade within a panel.

Conditional Lognormal Distributions—Parker, et al., (1979) made an extensive geostatistical study of the Imouraren uranium deposit, located in Niger. Two populations are present, a barren population comprising 43% of composites and a mineralized population comprising 57% of composites (Fig. 8). Ore and waste are commingled. Mine planning panels were chosen to be 50 × 50 × 12 m (164 × 164 × 39 ft) or approximately 64,000 t (70,500 st). Within each of these panels are 1000 selective mining units [each a 64-t (70-st) truck load] as shown in Fig. 14. The spacing of the holes given in the figure is representative. The probability distribution, conditional on the data, for each of the selective mining units shown in the figure was calculated. If this probability distribution is extended into the surrounding 4000 t (4400 st), it may be considered a conditional frequency distribution of selective mining units in the vicinity. If all 16 conditional probability distributions are combined, the con-

ditional frequency distribution of all the selective mining units within the panel is obtained (see Fig. 15).

To obtain a conditional probability distribution for a selective mining unit, the following assumptions were made:

- 1) The barren population is independent of the mineralized population. This assumption was verified by cross-variogram analysis.
- 2) Selective mining units are either all barren or all mineralized. This assumption was verified by examining pairs of samples at the same level in close-spaced twinned holes.
- 3) The mineralized population is multivariate lognormally distributed. This assumption could not be checked; however the successful local cross-validation indicates the assumption is not inconsistent with the data.
- 4) The mineralized selective mining units are lognormally distributed and multivariate lognormally distributed with the composite data. From a mathematical point of view, these hypotheses are inconsistent since the sum of lognormal distributions (aggregation of composite supports within selective mining units) are not lognormal. When the difference in variance is less than 15%, the assumption has been shown to work well in practice. This assumption could not be checked. On a global basis the results agreed well (within 5% of an independently globally adjusted frequency distribution of selective mining units).

Fig. 15. Conditional probability distributions for selective mining unit grades in the panels shown in Fig. 14 (Parker, Journal, and Dixon, 1979).

The theory used is developed in Journal (1980). Its application is described in Parker, et al., (1979). In brief, a conditional probability distribution is characterized by:

p^* = the ordinary kriged estimate of the indicator; 1 if composite is mineralized and zero if not.

z_{minz}^* = the mean of the conditional lognormal probability distribution of the selective mining unit, given it is mineralized.

σ_{minz}^2 = the variance of the conditional lognormal probability distribution of the selective mining unit, given it is mineralized.

The formulas for z_{minz}^* and σ_{minz}^2 are given by:

$$z_{minz}^* = \exp \left[\sum_{i=1}^n \lambda_i y(x_i) + \frac{\sigma^2 - \sigma_{smu}^2 + \sigma_{ok}^2}{2} + \mu \right] \quad (43)$$

$$\sigma_{minz}^2 = (z_{minz}^*)^2 \exp [\sigma_{sk}^2 - 1] \quad (44)$$

where $\sum_{i=1}^n \lambda_i Y_i$ is the ordinary kriging estimate using logarithms of composite grades $y(x_i)$ at location x_i , σ^2 is the variance of logarithms of composites, σ_{smu}^2 is the variance of logarithms of selective mining unit grades, σ_{ok}^2 is the estimation variance of ordinary kriging using logarithms of composite grades, and σ_{sk}^2 is the estimation variance of simple (unconstrained) kriging using logarithms of composite grades. This system is:

$$\sum_{i=1}^n \lambda_i \sigma_{ij} = \sigma_{j, smu}$$

μ is the Lagrange multiplier used in the ordinary kriging system

$$\sum_{i=1}^n \lambda_i \sigma_{ij} + \mu = \sigma_{j, smu}; \quad \sum_{i=1}^n \lambda_i = 1$$

The recoverable reserves associated with each conditional frequency distribution for cutoff Z_c are:

$$\text{Accumulation} = Q_i^* = K_Q T_i^* G_i^* \quad (\text{metal content}) \quad (45)$$

$$\text{Tonnage} = T_i^* = K_T T_{inf} p_i^* P_{i, Z_c}^* \quad (46)$$

$$\text{Grade} = G_i^* = G_{i, Z_c}^* \quad (47)$$

where P_{i, Z_c}^* and G_{i, Z_c}^* are given by Eqs. 36b and 37b, and T_{inf} is the tonnage influenced by the conditional probability distribution. K_Q and K_T are conversion factors stated earlier. For the whole panel:

$$A_{\text{panel}} = \sum_{i=1}^n Q_i^* \quad (48)$$

$$T_{\text{panel}} = \sum_{i=1}^n T_i^* \quad (49)$$

$$G_{\text{panel}} = \sum_{i=1}^n T_i^* G_i^* / \sum_{i=1}^n T_i^* \quad (50)$$

As described by Parker, et al. (1979), it is important to cross-validate the variance of logarithms σ^2 locally. This cross-validation can be done by kriging logarithms of composite grades, that have been temporarily removed from the dataset, using logarithms of surrounding composites as data. Within an area of the deposit the reduced errors of logarithms are calculated:

$$e_i = \frac{y_i - y_i^*}{\sigma_{i, ok}} \quad (51)$$

The deposit variogram with sill σ_o is used to do this kriging, and predict $\sigma_{ok, i}^2$. The average value of e_i^2 is computed:

$$w^2 = \frac{\sum_{i=1}^n e_i^2}{m} \quad (52)$$

Then the local variance of the logarithms of composite grades is estimated to be $w^2\sigma^2$. The sill of the variogram of logarithms of composite grades is rescaled locally by w^2 .

It is also important to cross-validate the conditional probability distributions on a local basis. While this cannot be done on selective mining units prior to mining, it can be done on composites. It is the experience of the author that if the underlying data are approximately lognormally distributed on a local basis, the technique works well. If there is a departure from lognormality, biases of up to 20% in recoverable grade and tonnage may be produced, and the method must be rejected. To some extent the indicator-mineralized cutoff may be moved to make the mineralized distribution as lognormal as possible, but the important thing to remember is that cross-validation must be performed exhaustively to check that the method does not produce biased results. Fig. 16 shows the cross-validation for the Imouraren (Niger) uranium deposit.

As a final check, the global frequency distribution of selective mining units can be compared with the frequency distribution obtained by compositing the local conditional frequency distributions over the whole deposit. Prior to mining, this is the only cross-check that can be made to validate the reasonableness of the hypothesis of multivariate lognormality.

Disjunctive Kriging—Matheron (1976) proposed a solution to the problem of predicting local recoverable reserves that does not depend on any underlying assumptions of lognormality. This method, known as disjunctive kriging, was described by Marechal (1975) and was first applied to uranium deposits by Jackson and Marechal (1979). The reader is also referred to a related study by Sans and Martin (1983). The technique is involved mathematically and computationally. The frequency distribution of the data is transformed into a normal distribution. The variogram of the transformed distribution is calculated and modeled. Using kriging, combinations of hermite polynomials describing a pseudo probability density function of grade are produced for selective mining units. It has been observed that these pseudo density functions may attach negative probability for some grade intervals. In addition, where the distribution of grade is non-stationary, the method, as others that do not correct for this, may give biased results. To be useful it must, like the lognormal methods, be cross-validated and the transformation into a normal distribution repeated on a local basis if necessary. Journel (1982) and Verly (1983) have investigated simpler methods that do not attach negative probability to grade intervals using multiple indicator variables and multigaussian transformation methods, respectively. These methods differ from those previously mentioned in that they predict the frequency distribution of composite ("point support") values within a panel. An adjustment is then made to this distribution, similar to the affine or indirect lognormal method, to provide an estimate of recoverable reserves based on selective mining units. At present, these methods have not been tested on uranium deposits, but show promise of being more robust than the lognormal or disjunctive kriging methods. The formulae required and assumptions made are as simple or simpler. Judging from experience, an exhaustive cross-validation of results is still recommended.

Remarks—In the absence of detailed geology from very

Fig. 16. Results of cross-validation of conditional frequency distributions on 3-m (10-ft) support (Parker, Journel, and Dixon, 1979) "Actual" curves are based on distribution of over 7000 composites.

close-spaced samples, the cost of which would be prohibitive, the statistical approach to ore reserve estimation is preferable to the deterministic approach in that it mathematically characterizes the continuity of the mineralization. Despite their mathematical complexity, it must be recognized that the statistical models of reserves that are derived using these methods are geologically simple. In many cases these models must ignore changes in the distribution of grade, lithology, mineralogy, or structure, sometimes for lack of data, and in others because the mathematical model that would take them into account would be intractable.

There are as yet too few guideposts to be provided by reserve estimates calculated at various stages of exploration, development, operation, and exhaustion to make this section of the handbook complete. The character of the undeformed stratabound deposits is fairly well known, because of extensive mining experience. The metamorphosed and igneous deposits of the Athabasca (Canada), Northern Territory (Australia), and Rossing (Namibia) genre are far fewer, and newer. Early work on some of these deposits (J. O'Leary, personal communication) has shown that a thorough un-

derstanding of detailed geology may be required to produce reserve estimates that are locally accurate, and because of changes in the local distribution of the ore minerals, statistical models based on global variograms and frequency distributions may be inappropriate.

Reserves or resource estimates are of course desired by mining company managements at all stages of a deposit's history. It is well to bear in mind that the less data available, the more dependent the estimate is on underlying assumptions. These assumptions should not be left implicit in a variogram model or a polygonal boundary, but should be an explicit part of the reserve statement.

3.4.3 Coal Ore Reserve Estimation*

JAMES W. BOYD

INTRODUCTION

An accurate determination of the quantity, quality, and minability of a reserve is essential for any coal or mineral property valuation. The foundation of such a valuation is the reserve estimate; the roots are the exploration and geological programs. The exploration program incorporates a study of the surface geology, subsurface characteristics, sampling of the deposit for quality analysis, and previously mined areas. Reliability of the reserve is determined by the thoroughness of the exploration program and variability of the deposit. Considerations such as transportation availability, markets for the products, and environmental regulations also affect the value of a reserve.

In any valuation study, an engineer develops an estimate of the present-day reserve base, isolating the minable reserve from the gross resource. Present-day reserves are capable of being marketed and are minable within a reasonable time period by available technological methods. A clear distinction exists between a minable reserve and a gross resource. The United States Geological Survey (USGS) has developed standard definitions for differentiation between the two terms within the coal industry.

Reserve: Virgin and/or accessed parts of a coal reserve base which can be economically extracted or produced at the time of determination considering environmental, legal, and technological constraints. The term reserve need not signify that extraction facilities are in-place or operative. Reserves include only recoverable coal, i.e., coal that is or can be extracted from a bed during mining. Reserves are derived from the reserve base, which includes bituminous coal and anthracite 28 in. [71 cm] or more thick occurring at depths to 1000 ft [304.8 m], subbituminous coal 5 ft [1.5 m] or more thick that occurs at depths to 1000 ft [304.8 m], and lignite 5 ft [1.5 m] or more thick that occurs at depths to 500 ft [152.4 m]. Reserves also include thinner and/or more deeply occurring beds of coal of these types currently being mined (Wood, et al., 1983).

Resource: A naturally occurring concentration or deposit in the earth's crust, and in such forms and amounts that economic extraction is currently or potentially feasible. Tonnage estimates are determined by summing the estimates for identified deposits of coal 14 in. [35.56 cm] or more thick for bituminous and anthracite coal with less than 6000 ft [1829 m] of overburden and 30 in. [76.2 cm] or more thick for lignite and subbituminous coal with less than 6000 ft [1829 m] of overburden (Wood, et al., 1983).

From the USGS definition, it can be concluded that all coal reserves are considered resources, but not all coal resources are considered reserves. If coal prices increase and/

or new technology is developed, deposits classified as resources could become reserves. Governmental action, in the form of new legislation, and the development of additional markets also influence classification changes. The USGS system of reserve and resource classification identifies present-day minable coal reserves. The definitions are general in nature and require refinement based on the particular property being examined.

A reserve estimate is not simply an exercise in geometry to determine the total resource deposit, subsequently disregarding such factors as seam thickness and depth of overburden. Reserve calculations are oriented toward minability, which requires engineering experience and judgment.

Unless specifically requested, mining valuation studies are restricted to reserves. Resources are not included because some may be considered unminable and, if included in a valuation study, would distort the most important item to be addressed: namely, determination of the present-day reserve base. Resource estimation also creates confusion, particularly in nonmining professionals, and results are often misinterpreted and consequently misused.

Many factors are considered by a mining engineer when determining the present-day reserve base of a property. Primary emphasis is given to: geology, exploration, development of reserve parameters, transportation and markets, environmental considerations, and reserve calculation methods. The balance of this section will examine these topics.

GEOLOGY

Geologic factors influence the parameters selected for the final reserve estimate; therefore, a formal investigation of available published geologic data is mandatory for a reserve study. The USGS, USBM, and various state mining and geologic departments collect and assemble a wealth of information concerning geology, thickness of deposits, and mined-over areas.

The geology of the deposit and surrounding strata is studied in detail prior to formulating a reserve estimate. Determination of the thickness and consistency of the deposit is essential.

Geologic data from the subject property and others in the general vicinity are examined to determine the existence of geologic disturbances or anomalies. Published sources may reveal whether seam thinning is regular or abrupt in nature. Extreme geologic disturbances may eliminate the deposit from consideration or the reserve value may be heavily discounted.

Topographic relief influences reserve calculations. A gently rolling plateau or relatively flat horizon offers less difficulty for surface mining than a high relief escarpment, which can negate cost-effective surface mining. Surface slopes limit the maximum bench width utilized during surface mining. Topographic relief also influences selection of a transportation method and siting of process facilities.

Studies of aquifers, flood plains, and drainage areas are essential to reserve determination. The presence of a large aquifer may hinder future mine development or cause additional pumping units to be installed.

EXPLORATION

Collection of published geologic data is the initial step in reserve determination. An exploration program (including core and/or rotary drilling, seam outcrop and mine measurements, and geophysical logging) further defines the geologic characteristics of the deposit and provides sufficient information for the mining engineer to formulate a reserve estimate.

When evaluating a reserve, the mining engineer is often provided with numerous seam measurements from the subject property. All drill hole and other pertinent seam data provided should have been observed and recorded by responsible drillers, geologists, and mining engineers. Before purchasing a reserve, a prudent buyer performs carefully designed check drilling to verify results. Absence of a well-defined exploration program decreases reliability of the reserve estimate, while a well-designed exploration drilling and sampling program supplies information on reserve quantity, reserve quality, overburden depth, optimal mining method to be utilized, outcrop/suboutcrop determination, seam structure, and mined-over areas.

Reserve Quantity

A predetermined core drilling and seam measurement program permits the engineer to develop seam thickness trends and minable reserve areas. Based on available information, minable seam heights for the deposit are determined and subsequently utilized in estimating reserve quantity. Additional discussion of reserve quantity is included in this section under the heading *Development of Reserve Parameters*.

Reserve Quality

Core drilling and bulk sampling permit the engineer to make a determination of coal quality.

Overburden Depth

Overburden depth is an important parameter considered in the final reserve estimate. The depth of overburden strata influences such items as selection of mining method, type of mining equipment to be used, strip ratios, blasting procedures, and minable limit of the reserve area.

Optimal Mining Method to be Used

Mining methods include underground, surface (contour or mountaintop), and auger operations. The exploration program provides the engineer with information which permits a selection of the most appropriate and cost-effective mining method for extracting the reserve.

Outcrop/Suboutcrop Determination

Seam outcrop is that portion of a deposit which appears at or near the surface of the ground. The outcrop is located using the results of the exploration program. Location (or absence) of an outcrop influences selection of appropriate mining methods. Outcrop location influences type of surface mining, i.e., whether the reserve is minable by the contour surface method or total removal can be utilized.

A suboutcrop was at one time an outcrop that, over the years, became covered with unconsolidated material. A "clinker zone" was also an outcrop but the coal became altered by ignition and burning.

Seam Structure

Seam structure refers to the structural dip (incline) of the deposit. Seam structure is used in conjunction with topographic relief to determine seam outcrop locations. Surface pit layout is influenced by seam structure.

Mined-Over Areas

Core drilling and field exploration may confirm existing mined-over areas or locate unknown mined areas, but these methods alone are not precise determinations. Other sources, such as aerial photographs and mine maps, are used in conjunction with exploration data to identify previously mined areas.

DEVELOPMENT OF RESERVE PARAMETERS

Parameters selected for calculation of a reserve estimate are site-specific. The following factors are important in developing an estimate of minable reserves: ownership or control, reserve classification, reserve category, seam thickness, overburden classification, in-place reserves, raw coal recovery, dilution, and processing and salable products.

Ownership or Control

Establishment of basic ownership or control rights is of primary concern in the calculation of reserves. The final reserve estimate categorizes minable acres and tons of the deposit by ownership classification.

A detailed title search should be performed by a qualified legal representative to verify ownership. If such a search is not feasible, the engineer states that representations of ownership have been provided and accepted without benefit of a title search. Ownership categories include:

Fee	Possession of complete mineral and surface rights
Surface Lease	Control by lease of surface rights
Mineral Lease	Control by lease of mineral rights
Surface Only	Ownership of surface rights
Mineral Only	Ownership of mineral rights
Federal Lease	Lease of mineral deposit and/or surface rights from the federal government
Adverse	Properties not owned or leased; future acquisition may be justified

Reserve Classification

Coal reserves are classified into three major categories (measured, indicated, and inferred) based on the reliable occurrence of the deposit.

The definitions which follow are oriented toward mine application and development and are generally in conformance with published government standards. Particular attention should be given to the criteria of having seam data points in a systematic grid pattern. Areas of measured and indicated reserves should not be shown around isolated drill holes.

Some latitude is warranted in particular cases, such as the use of a partially measured classification, which is applied where rotary drilling partially estimates the reserve. Use of all rotary holes to classify a property excludes it from the measured category as no information relating to seam quality is obtained. Deviations from the classification guidelines need to be clearly justified based on available data.

In cases where available seam information is comprised of a large number of thin or no coal data points, it is advisable to limit the reserve estimate to potential coal horizon acreage and classify the category as speculative, or simply not estimate any reserve due to insufficient data.

Fig. 1 depicts the classification system based on core holes, active mines, and other seam data points. The following provide a description of the three classification categories.

Measured reserves are tonnages computed from seam measurements as observed in diamond drill core holes, mine workings, and/or seam outcrop prospect openings. The

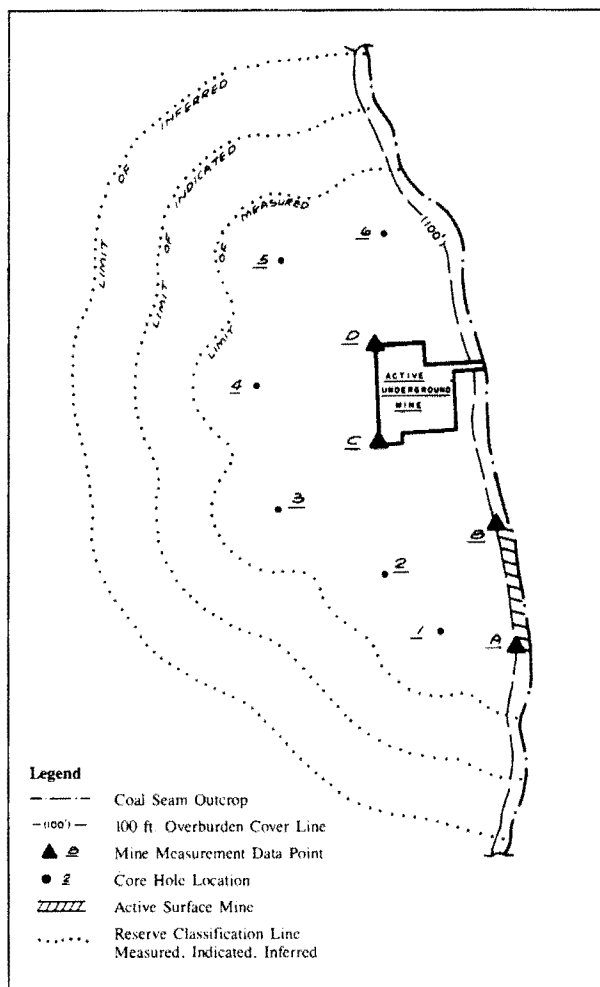

Fig. 1. Example of coal reserve classification system (not to scale).

points of observation are spaced to verify uniformity in seam thickness, physical character and quality, continuity of the seam horizon, and overall minability. The maximum acceptable distance between seam data points varies with the geologic nature of the seam being studied. Generally a distance of 0.5 mile (0.8 km) between points is recognized as the allowable standard for coal. If seam anomalies are present, this distance is reduced accordingly. For seams of known geologic continuity, where thickness and minability have been clearly defined over large areas by available seam data and historical mining experience, the maximum distance between points can be increased to 1 mile (1.6 km).

It should be noted that this definition is predicated on a systematic arrangement of holes in a grid pattern and does not allocate an area of measured reserve around isolated or wide centered holes. The computed tonnage is judged to be accurate within 20% of the actual tonnage.

Where data is not available (other than regularly spaced measurements along the outcrop) and the continuity of the outcrop is measured in miles (indicating the uniformity of the seam), an area of measured coal may be assigned extending a distance of 0.5 mile (0.8 km) (or the assigned maximum distance between seam data points) in by the outcrop. The same criteria may be applied to existing mine

workings provided these workings are extensive, regularly developed, and reveal the seam to be uniform and consistent.

Indicated coal tonnage is computed partly from inference of published geologic sources and use of available seam data points. Under normal conditions, the points of observation are a maximum 1 mile (1.6 km) apart, or approximately twice the distance established for the measured category.

Inferred coal tonnage is located beyond the limits of the identified classification. Reserves in this category should be identified by published geologic sources and sporadic seam data points. Inferred reserves are highly speculative and normally 0.75 mile (1.2 km) beyond known data points.

Reserve Category

Group 1: Reserves presently being mined or similar to those being extracted. The reserve has favorable potential for near-term development.

Group 2: Reserves which appear to be economically minable under favorable market conditions. Economic study and/or additional exploration is required to determine current minability. The reserve has marginal to good potential for near-term development.

Group 3: Reserves which appear to have uncertain mining potential because of less favorable seam height or mining conditions. A detailed mining study and market analysis are required. The reserve has doubtful near-term mining potential.

Seam Thickness

Seam data points should demonstrate uniformity in thickness. If extreme variations occur in total seam thickness or within the physical structure of the seam, reserve classification definitions are modified because of nonuniformity.

Based on seam thickness, a mining limit is assigned to the reserve. Seam data points having a thickness below the assigned mining limit are not used to classify the reserve. These measurements are actually demonstrating the unminable portion of the reserve.

A study of all available sources is made to determine whether seam thinning is regular and uniform or abrupt in nature. When abrupt thinning occurs, it is more reliable to project the limit of the minable or consistent coal area and assume normal seam thickness to the limit line. Reserves adjacent to the projected limit line are not considered measured unless data points are closely centered.

Want areas around seam data points recording no thickness measurement are projected midway between the no thickness point and adjacent minable thickness point.

Overburden Classification

Because the depth of overburden influences selection of mining methods and stripping ratios, reserves may be categorized by overburden depth. Use of overburden categories for surface minable reserves is complicated due to seam thickness and economic restrictions. Three frequently used classification groups are:

0 to 500 ft (0 to 152 m)

0 to 100 ft (0 to 30.5 m)
100 to 150 ft (30.5 to 45.7 m)
150 to 500 ft (45.7 to 152 m)

0 to 200 ft (0 to 61 m)
200 to 500 ft (61 to 152 m)

In-Place (In Situ) Reserves

In-place tonnage is the amount of coal in the ground prior to deductions for mining and processing losses. In-place reserves are calculated by determining the material specific gravity. Based upon the specific gravity, a ton per acre-foot (tonne/hectare/meter) or ton per acre-inch (tonne/hectare/centimeter) factor is developed. Multiplying that factor by the product of minable reserve acres and seam thickness yields in-place tons.

Raw Coal Recovery

A portion of the in-place coal reserve is not recoverable and is considered to be lost coal. The recovery percentage applied to an in-place reserve is affected by current mining methods and techniques, seam characteristics, classification of the reserve and depth of cover. If geologic anomalies are suspected, a reduction in coal acres or mining recovery may be justified. Mining recovery is also influenced by experience in neighboring mines operating in the same seam under similar mining conditions. A recovery percentage applied to in-place tons yields a raw recoverable product.

Dilution

Dilution is contamination of the deposit by foreign rock material or water. Rock partings are found either inside or outside the seam. In underground mining, thin in-seam partings are rarely separated during extraction. In-seam partings can often be removed in the pit during surface mining. Out-of-seam dilution is extraneous rock material, mined during the extraction process, that is not considered part of the minable seam.

Processing and Salable Product

Cleaning coal at a processing facility removes a portion of the impurities in order to produce an optimum salable product. A detailed sampling and analysis program provides the information necessary for calculating the clean coal recovery percentage which, when applied to the run-of-mine (ROM) tonnage, yields total clean coal product tons.

TRANSPORTATION AND MARKETS

Reserve marketability and delivered cost are influenced by the existing or future transportation network. An isolated reserve area may require construction of transportation facilities thus increasing costs.

Transportation from a mining operation can be by truck, belt conveyor, railroad, barge, pipeline, or an intermodal movement involving two or more of these methods. Competitive transportation options can increase the value of a property because transportation costs can be the highest component of the total delivered product price. Over half the delivered cost for sand and gravel and western coal is in the form of transportation costs.

In order for a reserve to be viable, markets must exist for the product. With no market, the deposit has only a residual value. Whether a market is unavailable because of the quality of the deposit or solely because of market conditions must be determined by the engineer.

ENVIRONMENTAL CONSIDERATIONS

Environmental topics are addressed during the valuation process. Type of mining influences environmental requirements.

Surface mining has come under the greatest amount of environmental scrutiny. Noise, air and water pollution, waste disposal, and land reclamation are some of the critical areas affected by environmental regulations. The Federal Surface Mining Control and Reclamation Act of 1977 (SMCRA)

defines guidelines for environmental control in the United States for coal mining operations. Many states have formulated mining regulations beyond the requirements of the federal government.

The burning of high sulfur coals by electric utility generating stations has led to the development of various proposals for acid rain legislation. As of this writing (1986), the federal government has been unable to formulate a comprehensive acid rain program. However, individual states such as New York and Wisconsin have passed acid rain legislation in an attempt to reduce sulfur dioxide emissions.

RESERVE CALCULATION METHODS

Major methods of reserve calculations include:

- Construction of isopach maps (lineal interpolation)
- Polygon construction (irregular grid construction)
- Computer-generated reserve (regular grid construction)

Construction of Isopach Maps (Lineal Interpolation)

This is the traditional method of calculating reserves. An isopach map defines, by means of contour lines, the varying thicknesses of a designed deposit. Based on structure contours, coal seams are correlated, minable seam thicknesses determined, and outcrop locations plotted. Seam measurement points are plotted on a map, and seam thickness is interpolated between existing data points. Fig. 2 is an example of a reserve map showing contour isopach lines. The isopachs are classified in increments, such as 36 to 42 in. (91 to 107 cm) and 48 to 54 in. (122 to 137 cm), and reserves are calculated based on these increments. Areas between seam thickness isopachs and other categories (i.e., classification, overburden cover lines, etc.) are calculated by planimetric measurement, and acres (hectares) of minable reserves are determined.

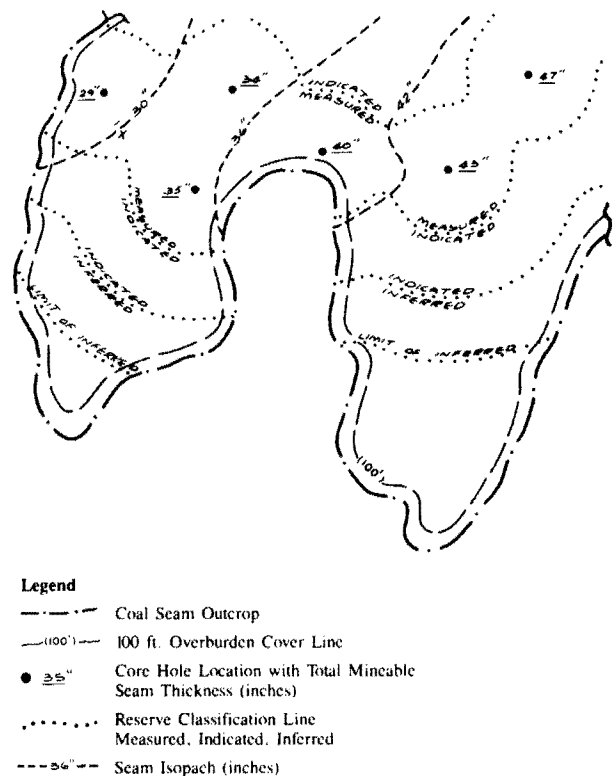

Fig. 2. Example of coal seam reserve map (not to scale).

The advantage of isopach lines is that they provide a reliable base for assigning seam thickness and permit the engineer to visually locate various thickness zones, a capability essential for mine design.

Polygon Construction (Irregular Grid Construction)

The polygon method of calculating reserves uses perpendicular bisectors to define areas of influence for each seam thickness data point. Each data point is assigned an area of seam thickness influence, and this area is planimetered and assigned a seam height based on the thickness of the seam data point. The polygon method is an accurate means of calculating reserves; however, thickness trends are difficult to discern. For mine planning purposes, the construction of seam thickness isopachs is recommended. Fig. 3 is an example of polygon construction.

Computer-Generated Reserves (Regular Grid Construction)

For this method, drill hole data and other seam measurements are collected and a data base is formed. The raw drill hole data include information regarding location, elevation, lithology, seam correlation, and quality. All collected data are entered into the computer; then a regular grid system is generated, with each grid composed of seam thickness, quality, elevation, topography, and other pertinent information. Maps showing reserve and seam quality data are constructed from the drill hole data base and displayed using cross sections and isopach contours. After map construction, the elevation extends to reserve calculation and mine planning. The following are developed from the data base:

- Coal/parting/seam thickness isopachs
- Seam structure
- Interburden isopachs
- Overburden contours
- Tons per acre (hectare)
- Quality isopleths

Legend

- Coal Seam Outcrop

Note: All reserves in this example considered measured.

Fig. 3. Example of polygon construction.

- Strip ratio
- In-seam waste
- Topography

Applying the traditional hand calculating approach limits the number of changes that can be made quickly during the course of reserve estimation. Computer-generated reserves permit flexibility and can reduce the amount of time required to reestimate a reserve.

For increased detail, geostatistics are applied toward reserve estimation to account for the spatial relationship between data points and provide mathematically determined confidence levels. As opposed to classical statistics, in which samples are assumed to be random and independent of each other, geostatistics recognize geologic variables as having some degree of continuity within an area. This is observed by closely spaced samples tending to be more similar than data points separated by larger distances.

These values, which can display both a random nature yet exhibit limited continuity are termed "regionalized variables." The underlying assumption of geostatistics is that distribution of the differences of regionalized variables is consistent throughout a deposit, being dependent only upon position of data points. The distribution variance is primarily used in geostatistics to measure the interdependence of sample values and their influence over adjacent areas within a deposit. A low variance of distribution differences indicates the data points to be highly related.

The variogram, or more commonly semi-variogram, is used to model the deposit and study the influence of samples by graphing variance or half-variance vs. distance between sample points.

Through use of the semi-variogram, it is possible to calculate the variance of error distribution resulting from assigning values of a sample point to a larger block of the deposit. It is obviously desirable to minimize this estimation variance, decreasing the probable error, thus producing a true or more accurate estimate. Errors are often assumed to be evenly distributed in order to apply standard confidence intervals.

For estimation of reserve, the deposit is divided into blocks with weighting coefficients assigned to nearby samples producing a value for each block. As with all estimation techniques, the sum of the weighting coefficients should be unity, thus providing an unbiased estimate. The geostatistical procedure that provides the set of coefficients that produces an unbiased estimate and minimizes the estimation variance is kriging.

The mathematics involved in construction of the semi-variogram and computation of the kriging system are tedious and well-suited for computer application. Several commercial geostatistical packages, with mapping and plotting programs to display data and results, are currently available.

SUMMARY

The foundation of accurate property valuation is the reserve estimate, a multi-faceted study which has been discussed in this section. Accepted standards guide the implementation of a reserve study, but site-specific characteristics determine the final applicable parameters. Favorable transportation options, available markets, and environmental considerations are necessary; if they are absent, the reserve may be of marginal value.

3.4.4 Iron Ore

RONALD M. HAYS, WILLIAM F. BETZLER, AND PERRY A. CANTON

INTRODUCTION

Both conventional manual and computerized methods are used to estimate iron ore reserves. Examples of application of these methods are presented for two taconite deposits on the Mesabi Iron Range: Biwabik Reserve and Prindle Reserve.

MESABI IRON RANGE

The Mesabi Iron Range, in northeastern Minnesota, is the primary source of iron ore for US steel mills.

The Biwabik iron formation of the Mesabi Iron Range outcrops for approximately 175 km (109 miles). This formation has a simple structure and is 100 to 225 m (330 to 740 ft) thick, striking east-northeast, and dipping 5° to 12° SE. A Z-shaped bend or cross fold, the Virginia Horn, occurs near the center of the Range. A major fault, the Biwabik fault, occurs in the eastern part of the Range. Minor local structural features are common. The Biwabik iron formation is divided into four stratigraphic units. From top to bottom, these are Upper Slaty, Upper Cherty, Lower Slaty, and Lower Cherty. The Virginia argillite formation and glacial material overlay the iron formation and the Pokegama quartzite underlies the iron formation.

The Biwabik formation has been altered and enriched in many areas, resulting in various ore types. Of principal importance are magnetic taconites, large low grade magnetite ore bodies. Important factors in estimating taconite reserves are geology, stratigraphy, concentrate grade, ratio of concentration, grindability, and stripping ratio. Blending also is important because of ore variability. Estimating reserves is complicated because ore and waste are intermixed in various horizons, with mining restricted because of equipment limitations.

Biwabik Reserve

The Biwabik Reserve, located between the cities of Gilbert and Biwabik on the eastern Mesabi Range, is a large magnetic taconite reserve controlled by Jones & Laughlin Steel Corp. The portion of this reserve considered in this study is designated as the "East Pit" and is approximately 3.0×1.5 km (1.9×0.9 miles) and has 64 drill holes. This East Pit has been estimated by both conventional manual and grid computerized methods.

Prindle Reserve

The Prindle Reserve, located north of the community of Parkville (city of Mountain Iron), is part of the "East Pit" of US Steel Corp.'s Minntac operation. There are 180 drill holes that extend over approximately 1.78×10^6 m² (440 acres) in section 36 except for the southeast quarter. Reserves have been estimated for 0.32×10^6 m² (80 acres) of the Prindle Reserve by both the grid and block computerized methods.

CONVENTIONAL MANUAL METHOD

The conventional manual method is the precomputer method of estimating reserves in flat or gentle dipping ore bodies such as the iron ores of the Mesabi Range. Topographic maps are made from ground or aerial surveys. Cross sections then are drawn to accommodate the existing drill holes and incorporate the planned drill-hole grid. Geologic

information and test data from drill-hole cores are added to cross sections and the configuration and stratigraphic layering of the magnetic taconite ore body are determined. For each drill hole, the minable taconite layer, or layers, are determined and the ore vs. waste ratio calculated and compared to the cutoff stripping ratio.

Using mining, metallurgical, and economic data available from taconite operations in the area, a mining plan is developed: a "first approximation" of the pit outline based on drill holes meeting the stripping ratio limitation is laid out on the map and cross sections. Cross-sectional areas of surface (glacial overburden), waste (nonmagnetic or lean magnetic formation), natural ore (if any), and magnetic taconite ore are determined by planimeter. Distances of influence are determined for each cross section. Based on cross-sectional areas, distances of influence, and material densities, the volumes and tonnages, including grade where appropriate, are calculated and tabulated. An overall stripping ratio for the pit is determined. The pit outline then is adjusted inward or outward to optimize ore recovery within the overall stripping ratio and also to minimize mining costs. Manpower requirements to determine reserves by this method limit the number of alternatives to be analyzed.

GRID COMPUTERIZED METHOD

The grid computerized method uses a series of computer programs to transform topographic elevations, drill-hole data, and geologic knowledge into a three-dimensional model of the deposit and then generates graphic displays and estimates surface (glacial overburden), waste (nonmagnetic formation), resources (minable and nonminable iron-bearing materials), and reserves (minable iron-bearing materials). This computerized system has great versatility, but requires considerable user interaction.

Topographic elevations normally are obtained by digitizing surface contour maps, but can be developed from survey data or drill-hole collar elevations. These topographic elevations are used to generate a grid matrix consisting of rectangular grids with surface elevation estimated for each grid node. For topographic surfaces, the grid matrix usually is generated by a distance-weighted function. The grid dimensions used for the surface topography grid matrix must be used for all subsequent grid generation. The grid matrix is a numerical representation of the surface topography. Topographic data must be generated for the entire area to be evaluated because a model can be developed only under grids having topographic elevations.

Raw drill-hole data are placed on a data base file and checked extensively for errors. Drill-hole data include identification, mining company, mine name, location, collar elevation, and incremental data. Incremental data include geologic horizon, geologic structure, chemical analyses, and beneficiation results and analyses.

The computerized system uses raw drill-hole data to prepare refined data base files for (1) mapping of stratigraphic units; (2) estimating and mapping surface, waste, and resources; and (3) estimating and mapping overburden (surface and waste), reserves, and stripping ratio. The system distinguishes between resources and reserves based on user-supplied economic related criteria.

The cutoff values for reserve estimates can be based on average or absolute values. Using average cutoff values maximizes reserve tonnage by converting resources to reserves if the combined values comply with the reserve classification criteria. Using absolute cutoff values minimizes reserve tonnage since resources cannot be converted to reserves. Using average cutoff values tends to increase the property's present value while using absolute cutoff values tends to increase the property's rate of return.

Based on raw drill-hole data and user-supplied criteria, the computerized system performs the following steps to generate a refined data base file for estimating and mapping minable reserves: (1) organizes data; (2) determines material classification (surface, waste, resource, reserve, direct shipping ore, or unknown) of drill-hole increments; (3) determines stratigraphic unit of drill-hole increments; (4) compiles drill-hole data for same material classification and stratigraphic unit; (5) compiles drill-hole data for surface, waste, resources, and reserves based on minimum minable thickness and maximum stripping ratio (considers waste both above and intermixed with resources and reserves); and (6) compiles drill-hole data for overburden, reserves, and bottom of pit.

Grid matrices then are generated based on the spatially distributed data in the refined data base files. Grid matrices can be generated by a variety of techniques, including (1) various distance-weighted functions with a variety of search procedures, (2) universal kriging, and (3) polynomial regression. Each grid matrix that is a numerical representation of a drill-hole parameter can be displayed as a contour map. Grid matrices are developed in a specified sequence and compared with previously generated matrices to assure compatibility of values in all grid matrices. The system also performs a statistical analysis comparing the calculated and actual values for drill-hole data parameters.

Using grid matrices, contour maps and cross sections can be generated for drill-hole parameters. Grid matrices also are manipulated to estimate volumes and/or tonnages of various materials.

For estimating reserves, volumes and/or tonnages of overburden and reserves are estimated for each grid and totaled for a user-designated area. The usual graphic displays are surface topography, bottom of pit, thickness of overburden, thickness of reserve, stripping ratio, and various cross sections.

Similar procedures are used to map stratigraphic units and to estimate and map surface, waste, and resources.

The grid computerized method provides numerical data, maps, and cross sections related to many parameters necessary for estimating reserves and subsequent mine planning.

BLOCK COMPUTERIZED METHOD

The block computerized method was developed for natural iron ores. An extension of that method has been adapted for use with taconite ores. This method combines some activities of the conventional manual method of estimating iron ore reserves with computerized activities.

A topographic map is prepared based on an aerial survey and field work. Cross sections then are developed with consideration given to geology of the formation and the planned drill-hole grid. Drill holes are plotted on cross sections and the iron formation is divided into layers based on geologic information, drill-hole chemical analyses, and beneficiation testing data. Next, "blocks" are delineated on the cross section by the mining engineer using equipment criteria and physical and geological characteristics of the pit area.

Blocks divide the layers into "slices" that are the basic unit of the block computerized method of estimating. Each slice is planimetered to determine the area and this information, along with all other pertinent data (drill-hole footage, geologic horizon, chemical analysis, etc.) related to this slice, is entered into the raw slice data base file. This slice data file is combined with a raw drill-hole data base file in a slice-block program to produce refined slice and block data base files for subsequent computer programs.

A computerized program could be developed that would give a reserve estimate tonnage based on blocks and appropriate criteria for the blocks. A computerized mining program has been developed that brings in additional file data on "lift and haul," equipment production rates, standard costs, etc. This mining program is a series of computer programs in which each block is first considered as waste (glacial overburden or iron formation) to be disposed of on a waste stockpile and, second, in the case of iron formation, as crude ore to the plant for processing. This allows for the determination by costs and earnings in each alternate as a means of block classification. The summation of blocks provides a reserve estimate tonnage with analyses plus certain cost and earnings data.

In taconite estimation, methods have been further computerized as compared to natural ore procedures. Basic data are taken from a data base file to plot required cross sections and maps. Computerized programs then assist in accomplishing the following steps:

- 1) Classifying each drill hole-increment as crude ore or waste based on parameters established by plant practice.

- 2) Economically evaluating data for each drill hole by combining waste and crude incrementally from the collar to the bottom and determining if the hole is economic and, if so, the location of the economic bottom of the hole; then assigning an economic index to the drill hole.

- 3) Contouring and plotting the economic indices to delineate the ore body limits, both as to lateral extent and bottom configuration.

- 4) Determining mining methods and designated bench elevations upon review by planning engineers using the previously determined ore body configuration; introducing the block concept of reserve estimation.

- 5) Creating and measuring slices with metallurgical data by analyzing drill-hole data from top to bottom; combining the slices to form blocks (this computer program eliminates the manual measurement of slices).

- 6) Combining blocks of about 100,000 t (98,400 lt) to form blast units of about 600,000 t (590,500 lt); combining blast units to form shovel units of about 4×10^6 t (3.9×10^6 lt) each.

These computerized programs give a versatile tool for mine planning. On a daily basis, however, closer control is desired. Mine engineers locate shovels daily as to coordinates and elevation. The computer then scans a 152-m (500-ft) radius of the location using all available data. Such data can consist of one to five drill holes, plus the magnetic iron information obtained from contoured susceptimeter readings. Using this information, the computer program calculates the best values to assign to that shovel location. Data from shovel locations are then blended to obtain the most desirable crude feed to the plant.

COMPARISON OF METHODS

Iron ore reserve estimates have been made for the Biwabik Reserve using conventional manual and grid computerized methods and for the Prindle Reserve using grid and block

Table 1. Comparison of Iron Ore Reserve Estimates

Method	Biwabik Reserve, t	Prindle Reserve, t
Conventional Manual	337×10^6	
Grid Computerized	344×10^6	48.0×10^6
Block Computerized		48.7×10^6

English equivalent: $1 \text{ t} \times 0.984\,206\,4 = 1 \text{ lt}$

computerized methods. The three methods have different approaches to defining parameters. However, to the extent possible, comparative reserve estimates are based on similar parameters, resulting in similar economic related criteria for minable reserves.

Table 1 presents iron ore reserve estimates for the Biwabik and Prindle Reserves using the three methods. The conventional manual method has been used for many years on the Mesabi Range and a good correlation exists between estimated resources using this method and actual mined crude

ore. Thus, reserve estimates made using the conventional manual method serve as the standard for determining reliability of estimates made by other methods. Reserve estimates for the Biwabik Reserve are based on average cutoff values and show an excellent correlation between estimates made by conventional manual and grid computerized methods. For the Prindle Reserve, absolute cutoff values are used, with an excellent correlation between estimates made by grid and block computerized methods. Thus, all three methods appear to provide reliable estimates of crude iron ore.

Table 2 presents iron ore reserve estimates for the Biwabik Reserve made by the computerized grid method with various parameters and procedures. Estimate 1 of $344 \times 10^6 \text{ t}$ ($339 \times 10^6 \text{ lt}$) uses the same parameters and procedures as the Biwabik Reserve estimate presented in Table 1. These reserve estimates show that the indicated changes in reserve classification criteria, minimum minable thickness, and grid dimensions did not substantially affect the reserve estimate. However, reducing maximum or cutoff stripping ratio from 3.25 to 1.50 reduced the reserve estimate from $344 \times 10^6 \text{ t}$ to $281 \times 10^6 \text{ t}$ ($277 \times 10^6 \text{ lt}$) as illustrated by Estimate 4. The first six estimates are based on average cutoff values while estimate 7 is made on absolute cutoff values and reserve classification criteria used for the Prindle Reserve. Thus, the estimate 7 with $288 \times 10^6 \text{ t}$ ($283 \times 10^6 \text{ lt}$) is less than other estimates except for estimate 4 with a 1.50 cutoff stripping ratio.

Table 3 presents iron ore reserve estimates for $0.32 \times 10^6 \text{ m}^2$ (80 acres) of the Prindle Reserve made by the computerized grid method. Parameters and methods changed in these estimates are stripping ratio and reserve limits or cutoff basis. As expected, reserve tonnage was greater with higher maximum or cutoff stripping ratio. Also, average cutoff values resulted in greater reserve tonnage than absolute cutoff values.

The conventional manual method has the advantages of (1) proven correlation between estimated reserves and actual

Table 2. Iron Ore Reserve Estimates Using Computerized Grid Method with Different Parameters and Procedures for Biwabik Reserve

Estimate	Parameters and Procedures	t

mined ores, (2) flexible decision-making criteria for special situations, (3) minimum equipment requirements, (4) no retraining of geological and mining personnel, and (5) maps and cross sections usable for mine planning. However, this method has the disadvantages of (1) high labor requirements, (2) high costs, (3) long time to complete (several months), and (4) high error potential.

The grid computerized method has the advantages of (1) low person-power requirements, (2) low cost, (3) minimum time to complete (a few hours after raw drill-hole data base file is created), and (4) low error potential. Indications are that reserve estimates by this method also correlate with actual mined ore. This is the quickest, easiest, and least expensive method of estimating reserves using a variety of parameters and procedures. The maps, cross sections, and data files generated by this method can be used for general mine planning, but are inadequate for detailed mine sched-

uling. However, the method can be modified for detailed mine scheduling. Disadvantages of this method are (1) lack of decision-making flexibility since the same criteria are used for the entire reserve, (2) need for computer, printer, plotter, and/or related equipment, and (3) need for specially trained personnel.

The block computerized method is between the other two methods in (1) labor requirements, (2) cost, (3) time to complete, and (4) error potential. Experience indicates that reserve estimates by this method are highly reliable and provide the vital decision-making tools to maximize the economic return of an operation. In addition to this advantage, this method also provides maps, cross sections, and data files to be used for detailed mine planning and scheduling. As with the grid computerized method, this method also needs a computer and related equipment and specially trained personnel.

3.4.5 Placer Sampling and Reserve Estimation

CLANCY J. WENDT AND STEPHEN W. THOMAS

Placer Sampling

One of the most difficult tasks associated with placer mining is the sampling of the deposit. More placer projects have failed due to inaccurate assessment of the reserves than to any other reason. Within the realm of placers, those containing valuable minerals with a high unit value are more difficult to sample than those with larger bulk, lower unit value minerals. Some items to consider when sampling a placer deposit are:

- 1) A relatively large size sample is needed for accurate valuation of the ground being tested. Placers are composed of many sizes of gravel that make a representative sample difficult to obtain.

- 2) When sampling placers for high unit value minerals such as gold, any error in mineral content of the sample will be magnified in the calculation of reserves.

- 3) Values usually are erratically distributed within the gravel mass. Therefore, some placers with a more uniform value distribution may be adequately assessed with a minimum number of samples, while a deposit with a high erratic distribution of values may not be adequately sampled regardless of how many samples are taken.

- 4) The investigation of a placer deposit should be made by or be under the direction of a person experienced in the art of placer sampling.

- 5) During a sampling program, items that must be observed and noted in addition to the sample size and valuable mineral content should include boulder size and number, clay content, bedrock conditions, water, frozen ground, false bedrock, and any other physical characteristics that would affect mining of the deposit.

Sampling Programs

The steps to be followed in approaching a placer sampling program are outlined below:

Reconnaissance: (1) check status of land ownership, (2) physical characteristics of area, and (3) research mining history of the area.

Choosing a Sampling Method: The main methods to consider are (1) existing exposures, (2) hand-dug pits or shafts, (3) backhoe trenches, (4) bulldozer trenches, (5) other machine-dug pits or shafts, (6) churn drill holes, (7) other drilling methods, or (8) bulk samples.

Special Problems Associated with Placer Sampling: These are (1) large rocks and boulders, (2) erratic high values, (3) uncased holes, (4) small diameter holes, and (5) salting.

Sample Processing or Washing: The considerations are the actual sample washing and the sample washing equipment.

Data Processing: Data processing consists of record keeping, reporting values, and assay procedures.

Reserve Estimation and Placer Valuation: Methods that can be used for reserve estimation and placer valuation are (1) block method, (2) triangle method, (3) polygonal method, (4) cross-section method, or (5) method of diamonds.

Conclusion: The placer sampling program report ends with a conclusion.

SAMPLING

The sampling methods outlined previously vary from simple grab samples on existing exposures to sophisticated drilling methods such as churn drilling. In this section, the various methods are discussed briefly and the applicability of each is indicated:

Existing Exposures

If existing exposures are available, they can be tested for potentially valuable minerals by taking a grab sample and panning the sample. Advantages of taking samples from surface exposures are the low cost and the speed at which the samples can be taken. The disadvantages are that you can only sample what is on the surface and no quantitative information can be produced.

Hand-Dug Excavations

These may be pits, trenches, or shafts and are suited to dry, shallow ground. This method of sampling is not used in the United States much today due to the high cost of labor but it can be effectively used in remote parts of the world where trained labor is not available or general labor is relatively cheap. The method provides a good bulk sample and is often used to verify drilling results by sinking a shaft over a drill hole. Bedrock values and characteristics can also be accurately determined when the excavations are sunk to bedrock.

Backhoe Trenches

Backhoes are a very versatile piece of equipment for sampling relatively shallow, up to about 6-m (20-ft) deep deposits. Backhoes are mobile, fast, can dig fairly hard ground, and are inexpensive compared to hand-dug excavations. Once a trench is opened up, channel samples are taken by hand or by using the backhoe or a bulk sample can be made with all of the material from the excavation. For backhoe sampling programs, the ground must be fairly dry and stable. Care must be taken when using a backhoe or any mechanical equipment to keep all fuel and lubricants away from the sample material as sample contamination can result, causing the fine gold to float and thereby reducing the value of the sample.

Bulldozer Trenches

Bulldozers are best suited to work in ground where trenches are to be dug 3 m (10 ft) deep or less and are in dry, stable ground. The greatest advantage of prospecting placers with a large bulldozer trench is that the trenches permit good visual inspection of the ground. Other advantages and disadvantages are similar to those associated with backhoe trenches.

Other Machine-Dug Excavations

Machine-dug excavations are shafts or pits which are dug using powered equipment such as large augers, bucket drills, or clamshell-type excavators. Digging shafts with the aid of powered equipment requires experienced operators and suitable machine access. Dry, stable ground is also needed for successful sampling operations when digging shafts and pits.

Augers: for sampling placers can vary from small hand-held posthole size machines up to very large truck-

mounted machines. Augers are relatively inexpensive to operate and can provide large volume samples. The disadvantages of using augers are their inability to penetrate ground with boulders, gold sorting may occur with spiral-type augers, and their inability to perform in water-saturated ground.

Bucket or Clamshell Type Excavators: These machines are usually quite large in size and allow taking a fairly large bulk sample. The advantages of using this equipment are its ability to allow visual inspection of bedrock, use of caissons to hold the hole open, and the capability of obtaining a fairly accurate sample volume. The disadvantages are the need for good access for the large equipment and a fairly slow digging speed.

Churn Drills: Churn drilling is used in deep or wet ground where sampling by pits, trenches, or shafts is not feasible. The churn drill (Fig. 1) utilizes a heavy casing with a drive shoe at the bottom, a chisel-shaped bit, and a vacuum-type sand pump for removing the sample from the hole. There are three main types of churn drills that are differentiated by their size: the hand-held "Ward," the light "Hillman" or "Airplane," and the heavy "Bucyrus-Erie" or "Keystone" drills.

The advantages of using churn drills for sampling placer deposits are (1) the sample is very reliable; (2) equipment is fairly portable; (3) few mechanical problems are encountered; and (4) technical data and interpretative information are available.

The disadvantages of using churn drills are (1) very slow penetration rate, (2) large boulders create many problems,

(3) problems from "running" ground, (4) requires skilled operator and careful drilling techniques, (5) fairly small sample size, and (6) the larger equipment requires good access.

The churn drill is a tried and proven process for sampling placer deposits. Abundant information exists on both the process and method of sampling. Due to the churn drill's reputation for producing reliable sampling results, it is still the most popular method of sampling deep placer ground in use today.

Other Drilling Methods

Due to the slowness and high cost associated with churn drills, other drilling methods are being tested for placer sampling. Some of the other types of drills are the reverse-circulation, hammer, and rotary; the vibratory; and the resonant or sonic drill. Details of each drill type follow.

Reverse-Circulation: With a reverse-circulation drill, the sample cuttings are blown up the inner section of a double-walled pipe. This method of cuttings removal reduces the chances of sample contamination as compared to conventional drilling techniques that force the drill cuttings out between the drill pipe and the surrounding wall rock. The advantages of using the reverse-circulation drill are high penetration rates at a fairly low cost per foot, its ability to penetrate boulders, and the ability to drill fairly deep deposits.

The main disadvantages are the need for good equipment access and the sample may not be representative of the actual material being sampled due to sorting. The use of a combination of churn and reverse-circulation equipment would give the operator the advantage of both speed and reliability. A correction factor will be necessary in most cases for the reverse-circulation drilling results.

Vibratory Drills: Vibratory drills have been tried recently for sampling placer deposits. The vibratory drills developed to date are quite portable, very fast in fine grained materials, and a fairly undisturbed core is obtained. The disadvantages are the small sample size, blockage in the core barrel, inability to penetrate boulders, and reduced penetration rates in clay.

Resonant or Sonic Drills: These drills have also been developed fairly recently and the technology associated with this drilling method is still being tested. Advantages of the resonant drill are its ability to penetrate boulders, it is relatively fast, the sample is generally undisturbed, and the method has good depth penetration. The disadvantages are the need for good equipment access, fairly high operating costs, core may be lost if vibration is used to extract the rods, and the method can only be used in fairly competent ground.

Bulk Samples

Wherever possible, bulk samples should be taken in placer deposits having an extremely erratic value distribution such as in deposits where the valuable mineral is found as widely spaced nuggets. Bulk samples are also needed for pilot plant test work.

SPECIAL PROBLEMS ASSOCIATED WITH PLACER SAMPLING

Due to the physical nature of placer deposits with a mixture of material ranging from large boulders to sand, and the nature of the valuable mineral contained in the deposit with medium to high unit value minerals erratically distributed within the deposit, placers are extremely difficult to sample. As mentioned previously, more placer mines have failed due to improper sampling than due to any other cause.

Fig. 1. Churn drill for placer sampling.

Some of the special problems associated with placer sampling follow.

Large Rocks and Boulders

When sampling placers, there is a tendency to bypass areas containing many boulders or to sample the easily collected finer material around the boulders. In many cases, this is essentially salting the sample since the valuable minerals in a placer deposit usually occur in the finer material.

The most direct solution to sampling areas containing boulders would be to take samples large enough to contain a representative portion of the boulders to give accurate value estimates. Since it is not physically possible to take large enough samples to include the boulders in most sampling situations, how does one consider the effect of boulders without including them in the sample? The most common solution is to visually estimate the volume and insert a correction factor into the end sample volume calculations.

Erratic High Values

The methods used for estimating the value of placer ground rely on the assumption that the value found in a particular sample extends halfway to the next sample. While evaluation of ground having a generally low or fairly uniform average of values can be done using the standard reserve estimation methods, erratic high value samples in a deposit cause problems.

Methods for adjusting erratic high values so an overevaluation of the ground does not occur includes resampling erratic areas and using the lower value determined or determining what the highest reasonable value should be and then keeping all sample values within that limit.

Uncased Holes

The use of uncased drill holes should be discouraged in placer sampling, especially in sampling ground with a high unit value mineral. If uncased holes are used, there is a tendency to unintentionally salt the sample and get overvalued sample results. This problem arises due to the fact that without casing, an excess of material can get into a sample without the evaluator knowing where, within the hole, the material came from. An exception to always casing drill holes is when drilling frozen ground. If the ground being sampled is well frozen, casing is usually not used.

Small Diameter Holes

Due to the large "nugget effect" associated with sampling ground containing high unit value minerals, the use of small diameter drill holes is not recommended for sampling deposits for gold, platinum, etc. When sampling deposits that have fine-grained material and contain low unit value minerals, small [50 mm (2-in.) diameter] holes may be used.

Salting

Salting of samples can occur intentionally or unintentionally. Intentional salting is the deliberate addition of valuable mineral to a sample. Unintentional or innocent salting is usually the result of careless or improper working procedures. No matter how salting occurs, the results can mean the failure of a project after many thousands or even millions of dollars have been spent bringing a property into production.

SAMPLE PROCESSING OR WASHING

Sample Washing

Once a sample has been taken from a placer deposit, it must be washed to separate the valuable mineral from the

waste material. The valuable mineral thus separated is then weighed to determine the value of the ground being tested. Most washing devices use some type of riffled surface to retain the heavy minerals as the lighter waste material is washed away. In dry washers, a current of air floats away the lighter material while leaving the heavy minerals behind.

No production equipment designed for the recovery of heavy minerals actually recovers 100% of the mineral. Because of this, it is important to select a sample washing system that will indicate the commercially recoverable mineral content of a sample. Other essential features of a sample washing system are low initial cost, easy maintenance, easy transport and setup, acceptability of a wide range of material sizes, efficient washing of the sample, efficient use of available water, ability to process large and small samples, good mineral recovery, ease and speed of cleanup, and reliability.

Sample Washing Equipment

Miner's Pan: The old-fashioned gold pan is still the most widely used device for washing small placer samples. The pan is well suited for washing small samples but is not well suited for handling samples over 13.6 kg (30 lb) or if samples are taken very frequently.

Sluice Box: A sluice box (Fig. 2) is generally defined as an elongated wood or metal trough equipped with traverse riffles through which alluvial material is washed to recover the heavy minerals. Sluice boxes are sometimes, but erroneously, called "long toms."

The function of riffles in a sluice box is to retard the movement of heavy minerals allowing them to settle while the lighter material flows on through the sluice. Carpeting is often used under the riffles to increase the recovery of fine gold. In some operations, mercury is placed in the riffles to enhance gold recovery.

Rockers: A rocker (Fig. 3) is a short, sluicelike trough with curved traverse supports that permit it to be rocked from side to side. A flow of water, aided by the rocking motion, carries the material down the trough where the heavy minerals are trapped by riffles. Rockers have been used almost unanimously for washing samples by the dredging industry. A rocker requires less water than a sluice and is capable of recovering very fine gold.

Dry Washers: Dry washers are used in arid regions where water is scarce and a "dry" recovery plant is proposed for production. The dry washer uses a bellows to blow air up through a sluice box with a porous bottom, causing the lighter material to progress down the sluice while the heavy minerals are trapped behind the riffles. In order for a dry washer to work efficiently, the feed must be very dry. Damp, sticky material cannot be processed until it is dried. A typical dry washer is shown in Fig. 4.

Other Washing Equipment: In addition to the previously discussed washing equipment that has been used since the early years of placer mining, there are two other types of washing machines that have come into use relatively recently.

The "Denver Gold Saver" and other comparable machines utilize a revolving trommel screen to separate the coarse and fine materials with the fines going to a shaking riffle for separation of the heavy minerals. The advantages of the "Gold Saver" type of system are its ability to process relatively large samples and to recover fine gold.

A second machine that has been used for about the last 40 years is the mechanical pan. Once the coarse material in a sample is screened from the fines a mechanical panning device can collect the heavy minerals. As the name implies, the equipment is designed to duplicate hand panning.

SURFACE MINING

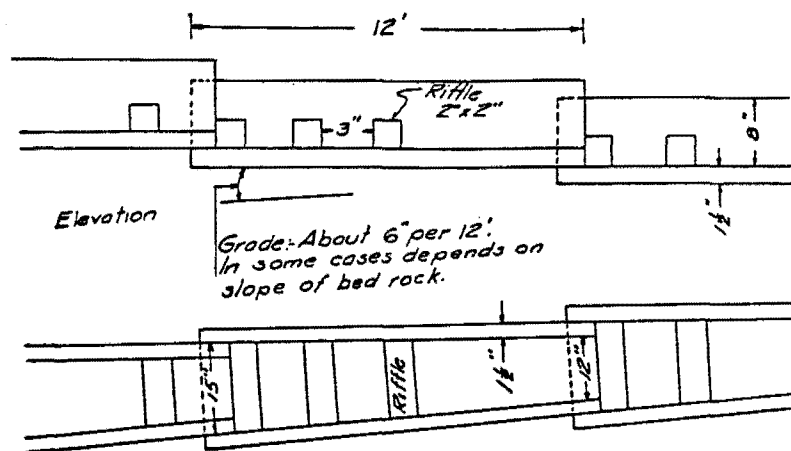

Fig. 2. Sluice box design (upper panel) and general sluice arrangement (lower panel).

DATA PROCESSING

Record Keeping

Accurate, systematic records must be kept for proper placer evaluation. As an example, data that must be recorded on a log sheet when churn drilling a placer gold deposit includes:

- 1) Name of property
- 2) Location
- 3) Date
- 4) Drill-hole line number
- 5) Hole number
- 6) Hole collar elevation
- 7) Time (time of day is given for each bailing. A summary of time consumed in drilling, pulling, moving, repairs, and delays is also given)
- 8) Depth of the drive shoe for each sample interval
- 9) Depth of pumping for each drive or sample interval
- 10) Total hole depth
- 11) Core rise in the pipe for each drive
- 12) Core left in the pipe after pumping, i.e., the plug thickness
- 13) The length of core removed
- 14) Volume bucket measurement
- 15) Classification of colors (count the number of No. 1, 2, and 3 colors)
- 16) Estimate the gold weight based on the color count
- 17) Formation (note the visible physical characteristics of the formation being drilled)
- 18) Depth and nature of overburden
- 19) Labor used
- 20) Depth of the pay gravel
- 21) Depth to bedrock
- 22) Nature of bedrock
- 23) Thickness of pay zone
- 24) Diameter of the drive shoe
- 25) Theoretical volume of core removed
- 26) Measured volume of core removed

Fig. 3. Rocker for placer sample washing.

- 27) Weight of gold recovered in milligrams
- 28) Fineness of gold
- 29) Drive shoe constant used in calculations
- 30) Value in cents per cubic meter (cubic yard)
- 31) Price of gold used in calculations
- 32) Signature of the driller, panner, and helper

It is essential that detailed records are kept as they will be used to determine the value of the deposit as well as to determine its minability. Information included in the drill logs will also be used in selecting a mining method.

Reporting Values

In the United States, the volume of placer material is always reported as bank cubic yards. The value of ground in gold placers is reported in cents per cubic yard as well as in milligrams of gold per cubic yard. The fineness of gold and the price used in the value determination are also reported. Minerals other than precious metals are reported in kilograms per cubic meter (pounds per cubic yard), percent, or the particular unit customarily used for the commodity in question.

Splitting Samples

When a gold or other high unit value mineral sample is taken, it should never be split or reduced prior to assay determination. Any attempt to divide a sample to reduce its volume will yield erratic assay results. When dealing with fine size placer minerals having a low unit value, a reduction of the sample size by mixing and splitting is an acceptable procedure.

Assay Procedures

At this point, the procedures for determining the value of a sample need to be discussed. The only correct way to determine the amount of valuable mineral in a placer sample is by weighing. After the volume of the total sample taken has been determined, the amount of valuable mineral in the sample is measured by weighing. After the sample volume and valuable mineral quantity have been determined, a value can then be placed on the ground represented by that sample. It should be noted that placer samples should never be fire or AA assayed. The only time fire assaying is acceptable is to determine the fineness of the gold.

RESERVE ESTIMATION AND PLACER VALUATION

After samples have been collected, washed, and assayed, reserves for a deposit can be estimated. There are many placer reserve estimation methods available. Some of these are the block, triangle, polygonal, cross sectional, and diamond methods. The figures with each description graphically demonstrate these methods.

Block Method

The value using the block method (Fig. 5) is calculated as follows:

- 1) Find the volume of each block, length times width times depth.
- 2) Multiply the volume by the value per cubic meter (cubic yard) in each block.

Fig. 4. Dry washer.

3) Find the sum of all the weighted values to obtain the total value.

4) Find the average grade by dividing the total in step 3 by the total volume to obtain the value per cubic meter (cubic yard).

Triangle Method

If Fig. 6A is used, the the method of calculating the value of the section is:

1) The volume equals the average of depth of the three drill holes times the area of the triangle.

2) The average gold content is equal to the gold value of each of the three holes times the depth of each of the holes divided by the sum of the depths of the three holes.

3) Total volume equals the summation of values in step 1.

4) Total gold content equals the total volume in step 3 times the average from step 2.

5) The average grade equals the value in step 4 divided by the value in step 3.

Fig. 6B is used when the pay streak is parallel to the long dimension of the triangles. The method of finding the value is the same as Fig. 6A.

Polygonal Method

Either method may be used in finding the value using polygons. There may be need either for regular or irregular drill spacing. Fig. 7A is for regular polygons and is calculated as follows:

1) The total volume equals the sum of the volumes of the individual polygons. Find the volume of the polygons by multiplying the area of the polygon times the depth of the drill hole.

2) Total gold content equals the sum of the grades of each hole times the volume of each polygon.

Fig. 5. Block method.

Fig. 6. Triangle method.

3) Average grade equals the value in step 2 divided by the value in step 1.

The volume (area) of each irregular polygon in Fig. 7B may be found by using a planimeter or by dividing the polygon into regular triangles and rectangles.

Fig. 7. Polygon method.

Fig. 8. Cross section method.

Cross Section Method

This method is very similar to that of the triangle and may be used as a check:

1) Area of a cross section (A in Fig. 8) is the average of the depths of the boreholes $(d_i + d_j)/2$ times the distance between the boreholes (W).

2) The total volume is one-half the sum of the areas of all individual sections A and B times the distance between the traverse (L).

3) The total gold content is the sum of the gold contents of each section. The gold content of a section is the volume of the section times the value of the drill hole.

4) The average grade is the value in step 3 divided by the value in step 2.

Method of Diamonds

The method of diamonds is much the same as that of triangles. The drill hole is located at the center of the diamond and apexes midway between drill holes on adjacent lines. This method is best used for regularly spaced holes. The total area is equal to the sum of all diamonds that may be treated as right triangles for all practical purposes:

1) Total volume equals the area of each diamond (A, Fig. 9) times the depth of each hole through the pay zone.

2) Total gold value equals the sum of the gold value in each hole times the volume of each diamond.

3) To find the value per cubic meter (cubic yard), divide the value in step 2 by the value in step 1.

Fig. 9. Method of diamonds.

CONCLUSION

There are many ways to sample and many methods to calculate the value of a placer deposit. It is important to remember to use care in sampling and to select the method that best suits the type of occurrence that is being sampled. Also, use the ore reserve calculation method that best typifies the configuration of the deposit and mode of deposition.

Feasibility Studies and Project Financing

Guerdon E. Jackson, Editor

4.1 Introduction

GUERDON E. JACKSON
BEE R. WAPLES, JR.

Feasibility studies, financial analysis, and project financing are necessary to bring together the large amount of basic data that will have been generated about a mining prospect over a period of time. As projects have grown in size, the amount of money required to bring a mine from the exploration stage to an integrated operation has increased, and it has become necessary to present a detailed plan to financial institutions for financing of projects. For many years mining companies provided funds from their reserves or profits to explore and bring new mines into production without turning to outside financing. This has generally not been the case in recent times.

It is the intent of this chapter to provide a basis for gathering and organizing required data in a systematic way and to provide guidelines and methods for varying depths of studies and analyses to meet a variety of conditions.

The feasibility study takes on many general meanings, from the commonly used term of *prefeasibility* to a full integrated feasibility study. In the first sense, prefeasibility can include order-of-magnitude estimates, whose only purpose is to provide a quick answer as to whether additional work and more detailed data should be investigated. In a multimillion dollar development, prefeasibility studies could be interpreted as milestone guideposts to assure that the project is still a viable entity.

The minerals industry has evolved a series of types of feasibility study estimates with varying degrees of accuracy that are used for different purposes. The prefeasibility study is often done early for comparative analysis in order to make decisions as to the continuation or rejection of a property, whereas a full feasibility study is normally produced for submittal to financial institutions to obtain the money for implementation of the project. When a feasibility study for financial purposes is required, then more than just a mine evaluation is involved. A complete analysis of mine, process plant, and infrastructure must be made in order to have a complete document that is acceptable to both the owner applicant and the receiving financial group.

If the capital required for a project is small in comparison to the assets of the owner's company, then a feasibility study accomplished within the owner's organization may be acceptable by the financial organization. On the other hand, if the capital expenditure is large and the total ability to repay the expenditure is predicted on the project being viable, then a recognized third-party company is usually contracted to make the feasibility study. Interestingly, most large banks or

financial groups have evaluation departments that employ mining engineers, process engineers, and economists who review the feasibility studies and recommend actions to their financial officers for acceptance or rejection.

Statistics indicate that a major ore body requires ten to fifteen years from discovery to production. The feasibility study is a major milestone along the way.

First and foremost among the feasibility study estimates is the ore reserve estimate. Without an ore body with a sound calculated ore reserve, there is no mine. Details on ore reserve calculations are addressed later in the chapter.

Development and exploitation of a mine are the base anchor and require imagination and experience. However, most ore bodies are complex; and processing of the ore is a necessary part of any project to produce a salable product. Many excellent texts exist for processing information: including the *Handbook of Mineral Dressing* by Taggart and many symposia publications by AIME, such as *Flotation* and *The International Symposium on Hydrometallurgy*. These are comprehensive metallurgical works that can be used to plan various flowsheets for processing the ore.

Laboratory testwork can confirm the proper method for processing the ore. It is also an advantage to the feasibility study if a pilot plant has been operated and the process data obtained from the laboratory has been confirmed with pilot plant backup.

Once the ore can produce a product, a market must be established. No product is acceptable unless there is a market for it, and many times, it is required that a market study be included in the feasibility study.

When it has been demonstrated that the ore can produce a marketable product, the infrastructure requires complete investigation. Table 1 is a checklist of the infrastructure items that must be investigated to assure successful operations. Depending upon the location of the ore body, the infrastructure problems may be severe. Domestically, many of the necessary services may be in place. On the other hand, in some foreign locations, the ore body must be able to pay for entire new communities, as well as all services. The burden generated by the infrastructure may be the pivotal influence on the feasibility study.

When all capital costs are estimated and indirect costs are included, a financial analysis is made. A section on the various elements to be considered is found later in the chapter.

New mining ventures frequently are characterized by rel-

atively large capital expenditures, long development times, and high commercial risk. Financial analysis thus becomes one of the key elements in the resource development process.

The financial analysis section in the chapter describes methods for establishing the necessary financial criteria. The time value of money, discount rates, accounting for inflation, and cash flows are discussed.

Methods of evaluating investments, including measurements of performance, sensitivity analysis, optimization, and risk analysis are discussed in detail.

To complete the section on financial analysis, taxation and depletion and their accounting are discussed with emphasis on practice in the United States. This section closes with a review of foreign project requirements, and other financial and economic considerations.

This chapter concludes with a discussion of project financing. A detailed review of general financing concepts reveals the sometimes controlling role of project financing in

resource development. Among the factors discussed is the role of the sponsoring mining company, financing costs, cash flow, credit evaluation, cash flow lending, and the development of the financing plan. Project viability factors and tax consideration are also reviewed.

Project financing is discussed in detail from the project planning and financing decision viewpoint. Credit terms and the general availability of creditors is reviewed. Significance of the debt coverage ratio, the impact of leveraging, and debt structures are discussed. A review of the impact of unanticipated capital cost overruns and the timing of borrowing conclude the discussion.

4.2 Feasibility Studies

GUILLERMO V. BORQUEZ

JAMES V. THOMPSON

INTRODUCTION

The purpose of a feasibility study is to demonstrate, on paper, the technical and/or economic practicability of a project prior to execution. The initial effort in this section is to establish a feasibility study model and to show how to develop its capital and operating cost.

Generally, surface mining feasibility studies are only a part of a larger all-inclusive feasibility study that might include beneficiation and processing as well as infrastructure facilities. An exception to this might be a mine where the ore is shipped to a nearby custom processing facility. There are several examples of this type of operation in the uranium industry in the western United States.

The objective of the feasibility study is usually economic and the methods employed are somewhat independent of the mineral commodity. However, in a country which might have massive unemployment, ample inexpensive hydroelectric power, and no domestic petroleum production, the objective might be the utilization of domestic resources for the benefit of the country rather than hard line feasibility in the traditional sense. For example, trolley operated haulage units might be selected regardless of the more favorable apparent economics of employing diesel trucks and imported oil.

BASIC DATA REQUIRED

General

Obviously the location, elevation, climatic environment, and local infrastructure should be known. The local infrastructure, including such items as housing, power and water availability, communications and transportation systems, labor availability and quality, is important advance information.

Nature of the Ore Body

Once the local setting of the ore body has been ascertained, its general nature should be studied to determine: 1) placer deposit, open or confined area; 2) rippable waste and/or ore; 3) hard rock waste and/or ore; and 4) geological vs. minable ore body.

Geological vs. Movable Ore Body

Geological Ore Body: The geological ore body generally includes all the body of material that contains the valuable mineral to be mined. The geological ore body may contain high and low grade ore zones that are not physically or economically minable, because of depth, isolation, or amount of included or covering waste.

Movable Ore Body: The movable ore body is that portion of the geological ore body that can be extracted at a profit. The limitations to the movable ore body may be stripping ratio, grade of ore, alteration of ore, depth, excessive water, or environmental considerations.

At the beginning of an operation, the movable ore body may not be completely delineated and, as operations proceed, more of the geological ore body becomes movable because of the learning curve, improved methods and equipment, and increases in the prices of the mineral product being mined.

Overall changes in technology and economics may also

cause the removal of ore from the minable category. A typical example of this was the vast reserves of wash and jigging ore on the US iron ranges in the North Central States. The advent of pellet technology and the resulting economic advantages in blast furnace operation brought about the abandonment of iron ore reserves that could only be beneficiated to an iron content in the low 50% Fe range.

Ore Reserves and Waste to Ore Ratios: In order to make a meaningful feasibility study of a site specific mining operation, it is necessary to have as much data as possible concerning ore reserves and the waste to ore ratio. While ore reserves are often based on surface trenching and pitting and at times indirect geophysical surveys, the most common exploration methods usually involve core drilling or air hole drilling.

A surface mining operation may produce any combination of the following products: ore, stripped waste, included waste that occurs between distinct bodies of ore, low grade material to be stockpiled for future treatment or treatment by a separate process.

It is, of course, necessary to quantify the amounts of each material to be mined and handled. Most copper mines in the southwest US will produce most of the above products and the same is true for some uranium mines and iron ore mines.

Selection of Mining Methods: While this subject is discussed in greater depth elsewhere in this volume, it is of course important to emphasize that the mining methods must be defined before a feasibility study can be undertaken. In some cases, for example in many placer operations, it is difficult to separate mining from concentration. A bucket line dredge, cutterhead dredge, bucket wheel dredge, or simple dragline operation usually dredges the material directly to the processing plant, which is frequently on board the dredge or floating alongside in the dredge pond.

Stripping: Stripping is discussed in more detail elsewhere in this volume. Most ore bodies require the removal of a waste covering of various depth; frequently the stripping operation involves different methods and equipment. Many coal and phosphate deposits are stripped by a large dragline or shovel which casts the overburden in windrows to the side of the exposed ore. Many uranium deposits in the West, particularly in Wyoming, can be stripped by ripper and scraper. The general objective of stripping is to expose the ore with minimum transport of stripping material, if transportation is required. Removal can be accomplished by conveyor systems, diesel, diesel-electric or trolley trucks, or even scrapers at times. Pit slurring and pipeline systems can be used where conditions are favorable. It is generally undesirable to crush and wet overburden material because of the slime problem. In the early days of California placer mining, hydraulic methods were employed for the removal of overburden but the resulting slime problem in river waters ultimately closed down these mines.

Ore Mining: The excavation of ore and its transportation to processing plant facilities may involve quite different methods and equipment than those employed in stripping. In the feasibility study, the ore mining portion may be considered separately if the amount of stripping is considerable

and the nature of stripping waste is quite different than the ore. For example; soft ores such as the phosphate ores of Idaho can be removed by ripper and scraper, and in some western US uranium mines, the ore is removed from small lenses by very selective backhoe excavation.

Production Scheduling: The extent to which mining is planned and scheduled will depend upon the end use of the feasibility study. If the study is destined to aid in the decision to accept or reject a property, a conceptual plan can be developed to arrive at quantities of ore and waste for costing purposes. On the other hand, if the study will be used to obtain funding, detailed plans should be prepared. For feasibility studies, this may involve computer-assisted calculation of ore reserves and computer-prepared plans and sections of the pit at various stages in the life of the surface mine. Computer modeling might be used to develop production schedules on a yearly basis for the first five years of the mine and on a five-year basis thereafter.

Definitions: A feasibility study must adhere to some carefully defined terms and these should be set forth at the beginning of any feasibility study report. The following are some important definitions.

Frame of Time—A feasibility study should be based on data and estimates for a one-year frame of time. Economic factors developed in the study will ultimately be used in some kind of economic analysis and these are always on an annual basis. The study may involve projected production rates over a number of years, but often the preliminary effort is to develop a full production model first. The total frame of time will depend on the life of the ore body and the economic criteria selected for the evaluation.

Operations Scheduling—It is important to define the annual hours of scheduled operation. Most very large mines are scheduled to operate 365 days per year, three shifts per day. However, certain sections such as the administrative group in the mine office may only work a 40 hour week on day shift only. Drilling and blasting is frequently scheduled for only five days per week, and often for only one or two shifts per day. Certain maintenance functions are more heavily manned on day shift and some may be on a 40 hour week basis. Some large mines in the United States will plan a total shutdown for ten legal holidays, frequently to avoid the premium pay required for operation during these periods. Labor is usually scheduled on a rotating shift basis and an effort is made to hold each employee to a 40 hour week. If the mine is to operate three shifts a day, seven days a week, it may be advantageous for the primary crusher to operate on the same schedule. From the standpoint of worker satisfaction, the best schedule is probably five days a week, two shifts per day. However, this can cause downstream difficulties. For very large mines, the storage necessary for 48 hours of mill consumption of primary crushed ore could be quite costly, particularly in severe winter climates.

It is not uncommon to schedule Monday day shift, both in the mine, primary crusher and concentrator, for scheduled maintenance, but this period is still part of overall scheduled time. A feasibility study should contain a table that outlines the mine schedule similar to the example shown in Table 1. The table should contain the following: scheduled days per year, scheduled shifts per day, scheduled legal holidays when the mine is shut down, average tons per day of stripping waste, average tons per day of ore, peak tonnage delivered to the primary crusher, and any other data pertinent to scheduling and production.

Factors Which Affect Productivity—Usually a mining feasibility study is concerned with a nonexistent operation. No

productivity criteria may be available, and frequently there is no similar experience in the area. The engineer works with judgment factors and, where possible, with experience from similar mines. The following are productivity factors and the definitions of these factors as they apply to feasibility studies. Operating mines may adopt different definitions.

Overall Job Efficiency—This is an hourly factor and it refers to the average number of minutes per hour that a machine or group of closely linked systems will operate while in service in the mine. Downtime during the hour is caused by the following: fueling and servicing of equipment; recess and lunch time, if lunch must come out of an eight hour shift; poor coordination of shovels, haulage vehicles; and crowding at the dump point.

Machinery manufacturers often talk about the 50-minute hour which results in an overall job efficiency of 83.5%. However, in many operations, a 45-minute hour and 75% overall job efficiency is more realistic.

Mechanical Availability—This is a term that may cause some confusion. In a feasibility study the concern is the mechanical availability of a machine assigned to the job. A machine can be 100% available simply because it is not scheduled to perform work. Loss of mechanical availability refers to time when the machine is substantially out of operation for repairs during the period of time when it would normally be scheduled for production. Machinery manufacturers tend to be somewhat optimistic about this number, but if an overall number could be picked for all machines in an average surface mine, it would probably be about 85%.

Generally, mines which are scheduled for a high percentage of total annual hours will have lower mechanical availability of scheduled units because there was simply less unscheduled time for maintenance. It should be emphasized that mechanical availability is related to time lost for maintenance when the machine was scheduled for operation and does not consider maintenance done on unscheduled time.

One Wyoming uranium open pit mine can document the fact that when a seven-day-week operation is used, scraper availability drops to about 65%. This means that a larger scraper fleet must be scheduled. If a five-day-week is used, scraper fleet availability increases and fewer machines are scheduled.

Annual Outage Factor—Most mines are subject to some kind of loss of production that can only be measured on an annual basis. Examples are: 1) electrical storms and snow storms which knock out transmission lines and substations and block roads; 2) flash floods producing uncontrollable water in the pit, haulage road damage, and slides in the mine; 3) moving large units of equipment, such as draglines and shovels, which may have to be *walked* by trailing auxiliary power; 4) external causes, such as breakdowns in the transportation systems, strikes in some other segments of the industry, and local labor disturbances.

Without a backlog of experience, it is recommended that some figure be used for annual outage factor if for no other reason than to indicate that the items have not been overlooked. If a 95% factor is used, meaning that 5% of the scheduled time is lost, this would be about 18 days in a mine scheduled for operation 365 days per year. The 95% factor is probably too low for a mild dry climate with an adequate public power system such as in Arizona; however, in a region of severe winter climate and heavy snowfall, 95% is probably reasonable.

Production Utilization—This is the figure often confused with *availability*. The concern here is with the amount of time on an annual basis that the machine is actually pro-

ductive. A machine may be 100% available, but it has no work to do.

For the purpose of feasibility studies, production utilization can be considered as the product of all of the foregoing. For example, if a mine is scheduled for six days per week, three shifts per day, minus ten legal holidays, 7,248 hours are scheduled for operation. The production utilization would be 0.75 (job efficiency) $\times 0.85$ (mechanical availability) $\times 0.95$ (annual outage factor) = 0.61 .

The production utilization for the preceding example is 61% of scheduled time, or $7,248 \times 0.61 = 4,421$ hours for most machines. This is a conservative figure, and if actual operating experience closely related to the project under study is available, such information should be used in preference.

Costing Hours—Operating and maintenance labor should be carried on a separate table as an annual cost and not assigned to each machine on an hourly basis. This will be discussed in more detail later. Ultimately, the annual use hours must be costed. The time lost in the overall job efficiency factor is not considered as free time and direct operating cost is calculated for the full hour. However, direct operating cost is not accruing during the downtime related to the mechanical availability factor. Also the machine is not accruing direct operating cost during periods of annual outage. The annual costing hours, for the example already discussed, are determined as follows:

Total scheduled hours	7,248
Mechanical downtime ($7,248 \times 0.15$)	1,087
Annual outage ($7,248 \times 0.05$)	362
Costing hours (rounded up)	5,800

The costing hours for each machine are multiplied by the number of machines or fraction thereof to arrive at total costing hours for the particular type of machine.

MACHINE SIZING, UTILIZATION AND SELECTION

This can be a major engineering effort involving computer programs and detailed studies, but information for such a study is seldom available in the preliminary feasibility phases. Much time can be wasted in detailed studies of equipment selection which affect the reliability of estimates to only a

Fig. 1. Reliability vs. effort (not an absolute analogy).

small degree (see Fig. 1, which is a hypothetical comparison of reliability vs. effort). It should be noted that many older open pit mines tend to get over-equipped and caution should be used when using equipment performance data from the large older mine as an example.

For the purposes of the discussion that follows, the reader is referred to Table 1. Using this information as a basis, equipment will be sized for a hypothetical operation in order to demonstrate the principles involved in preparing a feasibility study.

Drilling and Blasting

Some engineers prefer to design elaborate drilling patterns for feasibility studies, but generally this effort is unnecessary. There is usually not enough information on hand to design such a drilling pattern unless a pilot mine with full scale benches has been operated. Considering the contingencies employed in a feasibility study, it would be necessary to know all of the factors which affect drilling and blasting.

The most important factors to know or to assume, in drilling and blasting, are a reasonable penetration rate for the size of drill hole selected and the powder factor. The

Table 1. Basic Criteria, Hypothetical Open Pit Mining

Annual tons of ore and waste combined*	12,700,000
Annual legal holidays of total shutdown	10
Scheduled operating days per week†	6
Annual scheduled operating days§	302
Scheduled shifts per day	3
Scheduled hours per year, 302×24	7,248
Average daily tonnage 24 hr day (ore and waste)	42,053
Average hourly tonnage	1,752
Peak delivery to dumping points ($1752 \div 0.75$)	2,336
Overall job efficiency (45 min. hour)‡	75%
Average mechanical availability of scheduled time‡	85%
Annual outage factor	95%

* It is assumed that ore and waste are of the same physical nature and that the haulage distance for both is the same.

§ $52 \times 6 = 312 - 10 = 302$, however, $365 - 10 = 355$. In this case, 302 days have been assumed.

† Blasthole drilling scheduled 5 days, 2 shifts.

‡ Blasthole drills 60% and 80%.

Table 2. Selecting Number of Drills Required

Hole size	22.86 cm
Bench height	12.20 m
Hole depth	13.72 m
Total hole volume	0.56 m ³
Percent of hole depth filled with explosive	60%
Volume of explosives	0.34 m ³
Bulk density of explosives average	803 kg/m ³
Weight of explosives in hole	271 kg
Explosives factor, kg/t rock blasted	0.15
Tons broken per hole	1 807 t
Total tons ore and waste per year	12.7 Mt
Total holes per year, $12,700,000 \div 1,807$	7,028
Total length of hole, $7,028 \times 13.72$	96 424 m
Drilling rate while drilling the hole	25.9 m/hr
Actual drilling time required, $96,424 \div 25.9$	3,723 hr
Scheduled annual hours, 5 days, 2 shifts, 10 holidays	4,000 hr
Overall job efficiency	60%
Mechanical availability	80%
Annual outage factor	95%
Production utilization $0.60 \times 0.80 \times 0.95$	45.6%
Actual productive hours: $4,000 \times .456$	1,824 hr
Drills required: $3,723 \div 1,824$	2.05
Drills in use or available	2.0
Drills owned	3.0
Costing hours: $[4,000 - (4,000 \times 0.20) - (4,000 \times 0.05) \times 2.05]$	6,150 hr

Note: Time lost from overall job efficiency is not free time because most of it is for drill movement nonoperating time due to mechanical availability and annual outage factors are not changed for direct operating cost.

penetration rate is the meters drilled per hour while actually drilling, and the powder factor is the quantity of explosives required per ton of rock broken. With these two factors, a reasonable estimate can be made of the number of drills required.

Table 2 gives a typical feasibility analysis of drill requirements. Many of the line items are assumptions based on experience and in some cases field observation. Referring to Table 2, the hole size selected was 22.86 cm. Generally, larger holes require less drilling but may not yield as good fragmentation as a larger number of smaller holes. The hole depth is 13.72 m, 12.20 m is in the bench and 1.52 m is in the toe. The hole volume is 0.56 m³ and it will be filled to 60% of hole volume with explosives resulting in a total volume of 0.34 m³. These are arbitrary assumptions for a preliminary analysis.

The bulk density of the explosives is 803 kg/m³ and the weight of the explosive in the hole is 271 kg. This is a critical figure. The explosive factor is 0.15 kg of explosive per metric ton of material blasted and, therefore, each hole breaks $271 \div 0.15 = 1\,807$ t. The total tons of ore and waste to be blasted each year is 12 700 000. The holes per year are $12\,700\,000 \div 1\,807 = 7\,028$ holes per year. The total length of holes is $7\,028 \times 13.72 = 96\,424$ m.

Next, it is necessary to develop production utilization. This is the product of assuming an overall job efficiency of 60%, a mechanical availability of 80%, and an annual outage factor of 95%, yielding a production utilization of 45.6%. The low overall job efficiency accounts for moving the drill from hole to hole and the low mechanical availability accounts for the rough usage that blast hole drills may encounter.

The drilling in this example has been scheduled for two shifts per day, five days per week, minus ten legal holidays which results in 250 scheduled days or 4 000 scheduled hours.

With production utilization of 45.6%, the actual drilling hours equal 1 824. In this amount of actual drilling time,

96 424 m of drilling must be accomplished in a year. As shown in Table 2, the drilling could be accomplished by 2.05 drills which means that two drills would be in use and that the operation would own three drills. The third drill could be a deferred purchase after the first year. The costing hours for the drills would be 6 150 hours as shown by the calculation at the bottom of Table 2.

Secondary Size Reduction

This can be a costly activity. Every reasonable effort should be made to avoid secondary blasting methods by perfecting better primary blasting. However, it is often necessary to do secondary lump breaking of some kind. The modern trend is away from explosive methods. Drop balls and similar devices tie up an expensive machine, which may be slow to move.

Consideration should be given to hydraulic hammers mounted on a controllable boom and on rubber tires with self-contained on-board power sources. However, the hydraulic hammer may be expensive and underutilized. A secondhand or unused small dragline may be available which could be equipped with a drop ball, or a portable compressor and wagon drill might be used to drill a single hole in a large boulder for explosive breaking.

For the purpose of this example, a 0.40 m³/s compressor and a 1.18 cm track-mounted hammer drill has been selected. Such a unit can do other drilling jobs around the mine as well as secondary breaking. It is arbitrarily scheduled for 800 hours per year and there will be days when it is not used at all. Mechanical availability during scheduled time should be near 100%.

Loading Machines

A typical open pit loading machine is the standard cable operated dipper and boom shovel that has been in use for many years. A more modern piece of equipment with bucket capacities up to 15.3 m³ is the hydraulic front shovel. Since

1970, front-end loaders have been perfected to the point where they can be used in coarse blasted rock and can be either rubber tired or crawler mounted. For the purposes of this discussion, Table 3 gives the data required to select the number of 7.65 m³ conventional shovels. The factors used in Table 3 are judgment factors, in part based on manufacturer's information and in part on field observations.

Fill Factor: Fill factor is the percent of total capacity of the bucket that is actually filled during each pass into the muckpile. Coarse, poorly blasted ore usually gives a low fill factor. Finer ore and a relatively smooth bottom will give a high fill factor.

Actual Bucket Capacity: This is obtained by multiplying the fill factor by the bucket size.

Swing Time: Swing time is the time in seconds that it takes for the operator to crowd the bucket into the muckpile, pull out, turn, and dump into the haulage vehicle and return to the muckpile. The swing time for shovels is usually less than the similar cycle time for front-end loaders. However, this depends on the nature of the muckpile and the skill of the operator. Generally, conventional shovels will perform better in coarsely blasted rock than front-end loaders. Front shovels were first introduced in the mid 1960s and were mostly of European design. By the early 1980s most US manufacturers of excavating machinery were offering competitive designs. Sizes have ranged up to 19 m³, but the more common large size is about 15 m³. The advantages and disadvantages of front shovels compared to conventional cable operated shovels is hardly significant in a preliminary feasibility study. Many manufacturers make both types, and they have accumulated considerable operating data.

Continuous Capacity: The continuous passes per hour are determined from swing time and this multiplied by bucket capacity gives the hourly continuous production that would be expected. Continuous capacity is determined first and then discounted for production utilization later. See Table 3 for an example of this calculation.

Swell Factor and Bulk Density of Blasted Material: This is difficult to obtain even from operating mines. In the ex-

ample on Table 3, a swell factor of 0.67 has been employed, and this means that a bank m³ after blasting will have a volume of 1.49 m³. The weight of a bank m³ is 3.0 t, which means that the weight of a loose m³ would be $3.0 \div 1.49 = 2.0$ t. The tons per hour capacity of the loading machine at 80% fill factor on a continuous basis is then 6.12, giving a total of 1 571 t/h continuous capacity.

Production Utilization and Annual Shovel Capacity: Employing a 75% overall job efficiency, 85% mechanical availability, and 95% annual outage factor, the production utilization is 60.6%. The mining shovels are scheduled for three shifts per day, six days per week, minus 10 legal holidays which equals 302 days or 7,248 scheduled hours. When this is multiplied by the production utilization, the result is 4 392 hours of continuous production. Multiplying this number by the tons per hour capacity of the shovel, the annual capacity becomes 6 899 832 t. The annual production of ore and included waste is 12.7 Mt/a. Dividing the annual requirements by shovel capacity indicates that 1.84 shovels are required.

Two shovels would be in use, and rather than owning a third shovel, the operation could be equipped with a 9.18 m³ front-end loader, rubber tire mounted, which could back up the shovels and do other utility work. It can be noted in this calculation that the annual tonnage can safely be made when one shovel is shut down for short periods of time and production could be easy to sustain on an annual basis, if the front-end loader can be used as backup. To provide absolute assurance that loading will go on at all times, it would be necessary to equip the mine with more equipment than is justified when production is considered on an annual or even a weekly basis. Certainly, two shovels and a large front-end loader are adequate for the annual tonnage required.

Haulage Units

For the purposes of this example, 77.1 t (85 st) rear dump trucks will be used. The selection of an electric wheel or

Tons per minute, continuous 12.24×2.14	26.19 t
Tons per hour, continuous 26.19×60	1 571 t/h
Annual tons to be loaded	12,700,000
Annual shovel hours $12,700,000 \div 1,571$	8,084 hr
Annual scheduled hours, 3 shifts, 6 days, 10 holidays	7,248 hr
Overall job efficiency	75%
Mechanical availability	85%
Annual outage factor	95%
Production utilization $75\% \times 85\% \times 95\%$	60.6%
Productive hours $7,248 \times 0.606 =$	4,392 hr
Shovels required $8,084 \text{ shovel hours} \div 4,392$	1.84
Shovels in use	2.0
Costing hours $[7,248 - (7,248 \times .15) - (7,248 \times .05)] \times 1.84 =$	10,669 hr

Table 4. Haulage Truck Selection, 85-t (94st) Trucks

Cycle time continuous	12.5 min
Trips per hour, continuous $60 \div 12.5$	4.8
Tons per hour continuous 4.8×85	408 t/h
Overall job efficiency	75%
Mechanical availability	85%
Annual outage factor	95%
Production utilization	60.6%
Scheduled hours per year $(365 - 52 - 11) \times 24$	7,248 hrs
Productive hours $7,248 \times 0.606$	4,392 hrs
Annual production per truck year $4,392 \times 408$	1,791,936 t
Annual production required	12,700,000
Trucks required $12,700,000 \div 1,791,936$	7.09
Trucks in use	8.0
Trucks in fleet	9.0
Costing hours $[7,248 - (7,248 \times .15) - (7,248 \times .05)] \times 7.09 =$	41,111

Note: If trucks were capable of operating 100% of scheduled time only 4.29 trucks would be required. A fleet of eight trucks could in theory handle all the requirements without any spare, but if more than three trucks are out of service, the production schedule could not be met and a spare truck is provided to insure production if more than three trucks are out of service.

mechanical drive should be given careful study during the feasibility analysis.

Cycle Time: For the purpose of this example, it will be assumed that ore and waste are hauled the same distance (1 067 m one way) and that 12.7 Mt of combined ore and waste will have to be hauled each year.

The cycle time for trucks can be determined with greater reliability if an accurate profile is available over the haulage route. In the early phase of feasibility studies, this must be calculated from a hypothetical mining plan or assumed from limited information.

Manufacturer's catalogs contain data from which the speed for loaded and empty trucks can be calculated for actual distances and grades.

A typical truck cycle might be:

Maneuvering for position at the shovel	1.0 min.
Loading	3.0 min.
Accelerating the loaded truck	1.0 min.
Haulage to dumping point, 1 607 m away	2.5 min.
Decelerate and dump	1.5 min.
Return empty	1.5 min.
Total	12.5 min.

A critical portion of the cycle time is the time required to load the truck. In this example, the 77.1 t (85 st) truck might be somewhat large for a 7.65 m³ shovel because six passes might be considered excessive to some operators. However, the 77.1 t (85 st) truck is an efficient unit and fewer truck drivers would be required.

The use of computer programs to optimize truck and shovel combinations is recommended for feasibility studies when adequate data is available.

Determining the Number of Haulage Units: Table 4 gives the calculations for determining the number of haulage units without necessarily optimizing the shovel-truck combination and without details of the haulage road profile.

Support and Auxiliary Equipment

For the example under consideration, drills, shovels and trucks are the front line, regularly scheduled production equipment. Other support and auxiliary equipment is required as follows:

Rubber Tired Front-End Loader: In this example, a large front-end loader is proposed for emergency use when a reg-

ularly scheduled loading shovel is shut down for an extended period. This machine has a capacity of 9.18 m³ and its performance could be calculated in the same manner as the shovel in Table 3. It would probably have about the same fill factor, but its swing time or cycle time would be somewhat more. Depending upon conditions and the skill of the operator, it might have about 90% of the annual capacity of a 7.65 m³ shovel. As an alternative, the operation could be equipped with two smaller front-end loaders of lesser capacity.

The front-end loader is useful for removing isolated segregations of included waste or low grade ore. In any event, costing hours must be assigned to the front-end loader. Arbitrary scheduling might be one shift per day, six days per week, and with such light duty scheduling, its mechanical availability could be assumed to be 100% and the annual outage factor insignificant. When accounting for ten legal holidays and a six day work week, the scheduled annual days amount to 302, and the annual costing hours on a single shift basis will be 2,416 hours.

Rubber Tired Bulldozers: Where traction is no problem and there are no excessive lumps of very large coarse rock, a rubber tired bulldozer is very useful around an open pit mine. Compared to a track mounted dozer, the rubber tired bulldozer can be moved rapidly from one work site to the other.

Some of the duties which can be assigned to the rubber tired bulldozers are: 1) sweeping up fly rock around the shovel to keep a clear path for haulage trucks; 2) crowding the muckpile so that the dipper on the shovel may achieve a higher fill factor; 3) keeping a generally smooth haulage road in the immediate vicinity of the shovel, performing such duties as filling chuck holes that may accumulate water; and 4) leveling wind rows on waste dump.

Before the development of the rubber tired bulldozer, a track mounted bulldozer would be assigned to a large shovel. Much of the time this machine was idling without much work to do. Since the development of rubber tired bulldozers, if the shovels are not too far apart, one rubber tired dozer may service two shovels. For the purposes of this example, two machines of the 231 kW class are assumed. Such a machine may be oversized for some of the duties but it would have the capacity for more rigorous duty when required. There should be one rubber tired dozer assigned to the two

shovels and one other assigned to the waste dump. It may not be absolutely imperative that the waste dump station be constantly attended by one of the bulldozers. Backup is provided by a track mounted bulldozer and a motor grader, discussed later. The costing hours for the two bulldozers combined is about the same as the costing hours for the two shovels, which amounts to 10,612 per-year.

Track Mounted Bulldozers: The dozing power of a track mounted bulldozer exceeds that of the rubber tired machines and its principal duty would be in the pioneering of cuts for new benches and pit roads. In an emergency, it could be used on the waste dumps and around the shovels. For this example a machine in the 343 kW class is used, and if it were scheduled for use on day shift only, it should have almost a 100% mechanical availability during scheduled time and the annual outage factor would not be significant. The costing hours would be about 2,400 per year.

Motor Grader: A motor grader is indispensable for most open pit mines to properly maintain haulage roads. If the motor grader is scheduled for day shift only, six days per week, its mechanical availability should be almost 100% of scheduled time and the annual outage factor would be insignificant. The costing hours would be about 2,416. There are no tasks assigned to the motor grader that are so imperative that they cannot be delayed for minor maintenance purposes. In addition, both the rubber tired and track mounted bulldozer, and to a lesser extent, the front-end loader, can provide emergency backup for the motor grader.

Smaller Dump Trucks: There are frequent duties around a large open pit mine where smaller utility dump trucks can be used. In this example it is assumed that 32 t (35 st) trucks would be available for miscellaneous use. Among these uses are emergency use for ore haulage in case of unexpected multiple breakdowns of the main truck fleet and the haulage of road dressing material for the haulage roads. The total costing hours for the three trucks could be assumed to be about 2,400 hours.

Service Vehicles: Most surface mines find it necessary to sprinkle the haulage roads to control dust and, therefore, a water sprinkling truck is necessary. In a dry arid climate such as the southwestern United States, the truck may be used all year around; but in more humid northern climates, it might not be used for more than five or six months per year. Indeed, mud may be a greater problem than dust. For the purpose of this example, an arid dry climate is assumed and the sprinkling truck would be used for a few hours every day. For study purposes, assume 1,000 hours per year.

Most surface mines will have a field fueling and lubrication truck and a field repair truck with welding, hard facing, and cutting equipment on board. Some large mines may also have a field tire changing truck, but in most locations in the United States, the major tire manufacturers have service organizations very close by that can dispatch a truck from their shop to the mine to perform this service.

Supervisors and engineering staff are usually provided with pickup trucks. Haulage of explosives and the loading of blastholes can often be contracted in United States mines.

All of the aforementioned vehicles, with the exception of pickup trucks, are generally underutilized. Even in a dry climate the sprinkling truck would probably be in use no more than about 1,200 hours per year. The same applies to fuel and repair trucks, and for both of these vehicles, a combined allowance of 2,000 hours per year would be adequate for this example. It will be assumed that the mine in the example being discussed here will be equipped with an explosives truck whose scheduled time would hardly exceed

600 hours per year. For this example, no tire changing truck would be provided.

For a mine that moves a total of 12 700 000 t per year, there would probably be about eight pickup trucks for supervisors and engineers. Use of such vehicles will vary widely, but for the purposes of this example, it is assumed that the total usage would be about 10,000 hours per year.

Pit Drainage and Lighting: These items may add significant cost to the mining operation. Many surface mines which do not have natural drainage may have to resort to pumping water from low points in the pit. For this example, it will be assumed that the mine is developed on a self-draining hillside location. If an open pit mine is to be developed on relatively flat terrain, a great deal of drilling and hole pumping may be required to obtain an estimate of the quantity of water to be removed. Accurate information can be difficult to obtain in the preliminary phases. With sufficient information, projections of water quantities can be made by competent geohydrologists. Complex problems can be encountered where lakes must be drained, streams rerouted, and well points established around the active mining pit.

Most mines scheduling a night shift would have pit lighting. All of the equipment has attached headlights or floodlights. Most shovels and large blast hole drills are electrically operated, therefore, power is generally available in the pit and lights may be strung along the principal haulage loads. Portable floodlights can be placed in the shovel and dumping areas. Developing the equipment and cost for pit lighting is a straightforward engineering task and need not to be discussed in detail here. For the purpose of this example, it will be assumed that pit lighting is provided from the power distribution system in the mine.

Power Distribution: When shovels and blast hole drills are electrically powered, power distribution facilities from incoming power lines involve portable switch houses and trailing cables. While these units do not involve large operating costs, they are a significant item of capital cost. For the example being considered, three 1,000 ampere switch houses and four trailing cables of at least 457 m (1,500 ft) capable of handling 8,000 volts are assumed. Besides the secondary distribution system, the feasibility study must consider the requirements for incoming power and a loop around the pit, if necessary.

Radio Communication: Every mining operation today should make maximum use of two-way radio communications which is inexpensive in both capital cost and operating cost. A repeater station would be required which is located either on a high elevation of land or a tower so that maximum range may be obtained in the system. All supervisors' trucks, haulage trucks, field service, repair trucks, and shovels should be equipped with a two-way radio unit. Other units such as the rubber tired bulldozer, motor grader, front-end loader, and water truck might be included.

MAINTENANCE FACILITIES

General Maintenance Concept for Feasibility Studies

The ultimate objective of feasibility studies is usually economic and involves the development of capital and operating cost. Many large mining operations will have central shops that perform all the maintenance for the mine, concentrator, processing plant, railroad, port facilities, and town site, as applicable, on a work order basis. The difficulty with this concept in a feasibility study is that it becomes necessary to prorate maintenance costs in order to determine a maintenance cost for the mining department.

The preferred method for feasibility studies is to assume that the mining department operates its own maintenance facility for the use of the mine. In some instances this might include the primary crusher. For this example, it will be assumed that the maintenance facility is solely for the mine and under the supervision of the mining department.

Nature of the Facilities

Mine maintenance shops can vary from elaborate, fully equipped, enclosed, and heated facilities to simple open shelter in a mild climate. The location of the mine, the surrounding infrastructure, and transportation facilities to and from the supply centers affect the nature of the shop. In a remote area, in the subarctic for example, the mine shop would have to be enclosed and heated with the equipment and parts inventory necessary to sustain the operation with the supply centers located thousands of miles away. In a remote tropical area, the structure might be in open shade but the facility would have to be fairly complete.

In remote areas the mine shop will have to carry a large inventory of spare parts, be capable of rebuilding engines, transmissions, and electrical components. A tire recapping shop may also be required.

In mining districts such as the northern US iron ranges and the southwestern copper mining districts, suppliers maintain service centers in medium to large communities within the district. Tire service is often provided on a contract basis. Major machinery companies that manufacture open pit mining machinery keep stocks of spare parts nearby and can usually provide engines and transmissions on an exchange basis.

From the foregoing discussion, it can be seen that maintenance facilities are affected by the local infrastructure and climate conditions. As stated in the beginning of this section, information concerning infrastructure and climatic conditions is essential in the preparation of a feasibility study. For the purposes of the example referred to herein, it is assumed that the maintenance shop is in a mild climate requiring some minimum enclosure and provisions for restricted space heating.

Sizing the Maintenance Facilities

The maintenance facility usually involves a rectangular building with numerous bays along one long side. These bays are usually equipped with roll-up doors that remain open most of the time, weather permitting. The building should be high enough so that it can accommodate a haulage truck with the bed raised to the maximum vertical position. It is desirable for the building to be equipped with an overrunning bridge crane with the capacity to remove the largest engine. Heating can be provided on a *spot basis* with several types of heating devices.

In preparing a feasibility study it is important that supporting maintenance facilities not be overlooked. These include spaces for welding, electrical and instrumentation repair, and washdown. In remote areas requirements for oil reclaiming and components repair may be needed.

One of the important concepts to be developed during the preparation of the feasibility study is the amount of repair and maintenance work to be done at the mine. Because the cost of space and equipment can be significant and because the cost of downtime for equipment improperly maintained can become prohibitive to an operation, the repair and maintenance facilities should be developed in some detail during the feasibility process. See Table 5.

CAPITAL COSTS

Definition of Capital Costs

A general definition of capital costs would be those items of project cost that will be depreciated for capital recovery and tax purposes. Whether or not certain initial costs are capitalized or expensed is frequently influenced by management policy and income tax requirements. For example, the preproduction cost required to bring an open pit mine into production might be capitalized or expensed depending upon a particular company's policy. As a general rule most mining companies would prefer to expense these items if it resulted in a tax advantage that was allowed by law.

Items Specifically Included in Capital Costs: Generally, capital costs include: 1) exploration and other preproduction cost depending on management policy; 2) mining machinery including freight, erection, and initial spare parts inventory; 3) permanent structures such as maintenance shops, mine offices, and warehouse; 4) all of the equipment and initial supplies in permanent structures; and 5) operating capital.

For a complete mining facility which might involve concentrators, smelters, refineries, and other infrastructure, the list and definitions of capital costs would be more extensive.

Items Specifically Excluded from Capital Costs: This category also depends upon management policy and tax matters but, in general, facilities located outside the immediate area of the mine are normally excluded from feasibility studies.

Types of Feasibility Study Estimates

For the purpose of feasibility studies, four general types of estimates have been devised for both capital and operating costs. A summary of these definitions is included in Table 6. Generally, feasibility studies restricted to mining only seldom become overly involved with these definitions. With the exception of more detailed design for permanent facilities, the definitions vary only slightly from Type I to Type IV. There is no difference in a quotation for equipment obtained for Type I or Type II. Type III and Type IV might involve written equipment specifications. The feasibility study types are somewhat more applicable for complete feasibility studies that involve an entire project, not just the mining phase alone.

Mobile Mining Equipment.

In the preparation of a mining feasibility study, one of the most important items of capital cost is the list of mobile mining equipment. This list should include the following: 1) FOB factory cost of the machine fully equipped with all of the accessories required for the job; 2) dry weight of the machine; 3) export packing, if required; 4) installed diesel or electrical power, although not important for small vehicles; 5) freight from factory to job site, including actual deliveries to the job site; 6) import duties and special taxes; 7) job site erection cost; and 8) spare parts inventory.

Many of the above items are essential for operating cost calculations. The weight of the equipment may be required for freight calculations. In addition, if the weight and cost of a machine are known, a rough estimate can be made of the cost of another machine if its weight is known and if it is of the same order of complexity.

Most mining machinery in the United States originates in the middle west or the upper middle west, and inland freight charges in the United States can be estimated by contacting railroads and truck lines.

Table 5. Major Items of Shop Equipment

Item	Size	Qty	Unit Wt, kg

Import duties and other government assessments on overseas projects may require careful investigations. Even though foreign projects may be undertaken by mining organizations owned by the government, duties on imported equipment may be assessed.

Most large mining machinery arrives on the job in a knock-down condition. A large dragline, for example, can require many months to erect. Erection and start up of large mining machinery is usually under the supervision of a field engineer provided by the vendor. His service, if not included in the initial price of the machinery, will be an extra cost charged by the vendor.

Spare parts inventories can represent a significant capital cost; the cost of this inventory is an interest-bearing item. In the United States, where vendors maintain field service organizations, inventory may be kept to a minimum. On overseas projects, spare parts inventories are usually larger. Often an overseas project is being financed by some source of international funding and the tendency is to provide a large initial spare parts inventory since it may be difficult to

obtain government licenses to import spare parts once the project is operational.

For a preliminary feasibility study, 5% of the FOB factory cost of the machinery is adequate for estimating an initial stock of spare parts at US locations, but overseas projects may require as much as 10 to 20%.

Permanent Structures

Usually the permanent structures for an open pit mine are relatively simple architectural and structural designs. Unless the mine includes a crushing plant, the permanent facilities are usually a maintenance shop, mine office, warehouse, outdoor storage, fuel storage facilities, powder magazine and blasting material storage, and a changehouse. For a preliminary study, these facilities can be estimated by the square foot employing locally obtained unit costs. If the maintenance shop is to be equipped with an overhead crane, the building must be designed to include columns and crane rails for the support of the crane. Table 7 gives an example of a preliminary estimate for permanent structures for an

open pit mine. More detailed estimates, of course, require detailed design with quantity take offs.

OPERATING COST

Operating costs for a feasibility study should be developed for each element of cost. Caution should be exercised when using the operating costs of existing mines. Criteria may be obtained from existing mines, but even a primary feasibility study should document each item and group of operating costs.

If the feasibility study involves a surface mine only, the operating cost should include the highest level of resident management. If the feasibility study is for an integrated mining, concentrating, and smelting operation, the operating cost estimate should include the highest level of management

directly related to the mine. This would generally be the office of the mine manager. Generally, *front office* cost should not be prorated against the mining department.

Definitions

Generally, operating costs include: 1) supervision and labor, salaries and wages; 2) labor burden; 3) all expendable mining supplies; 4) operation of major mining equipment including maintenance parts; 5) electrical power; 6) allowance for mine department undistributed overhead such as office supplies, engineering supplies, and general maintenance supplies; and 7) local property taxes and insurances, in the case where the mine is producing ore for direct shipment to other utilization points.

Items which are generally not included in a mining fea-

sibility study are: 1) nonresident management and sales costs; 2) income related or other taxes, because these are matters to be addressed in the economic analysis; 3) depreciation, interest, and royalties, which also are to be addressed in the economic analysis; and 4) transportation of ore beyond the local dumping points.

Basis for Direct Operating Cost Calculations

Every attempt should be made to develop operating cost. Unit cost from other mines can be used as a credibility check, but the engineer should develop costs specifically related to the project involved in the feasibility study. Many items are judgment factors applied by the engineer to indicate that the item was not overlooked, rather than to demonstrate absolute accuracy.

Supervision and Labor: Labor rates should be the current rates employed in the area. If there is no current mining activity in the area, the labor rates should reflect the local wage rate structure.

In a unionized mining area, the local labor unions will publish labor rates. In the United States, union wage scales may show very little percentage difference in rates between various categories. A high degree of skill may not show a large difference over unskilled employees. This is not true in some of the developing countries where skills are rewarded handsomely as compared to unskilled wages, and this differential can be a matter of several hundred percent.

Supervisory and engineering personnel are usually paid a monthly salary, and such rates are not difficult to obtain. Local precedents should be followed where possible. In a surface mining operation, most of the supervisors with some exceptions are engineering graduates. The wage scale for supervisors may be higher than for engineers. It is not unusual for the engineering staff to be rotated through supervisory positions, and often the distinction between supervisors and engineers is difficult to ascertain.

The most important item in developing the labor cost is the manning table. It is generally divided into three categories: 1) supervision, engineering, and clerical; 2) equipment operators; and 3) maintenance people.

The manning table should always be on an annual basis. In the example which has been used in this section, the total annual scheduled operating hours are 7,248. It is assumed that all labor is paid for 52 weeks per year, 40 hours per week, or 2,080 hours. However, an employee, if allowed two

weeks vacation and five days sick leave, in addition to the 10 legal holidays, only works 1,872 straight time hours. If a position such as a shovel operator must be manned for all scheduled hours, it will require 3.87 employees for two shovels. If the operation were fully scheduled at all times, or 8,760 hours per year, the position would require 4.7 employees. For this example, 4.5 employees should be used as an average because it may be assumed that there are excused absences and employees with long periods of service that may qualify them for more than two weeks vacation. For example, there are eight trucks in the active fleet and these trucks must be manned for 57,984 hours per year; dividing these hours by 1,872 indicates a requirement of 3.87 drivers per truck, or a theoretical requirement of about 31 drivers. To cover the aforementioned extended seniority vacations and excused absences, the total truck drivers who would be paid for 2,080 hours per year would be at least 35 in number.

Similar reasoning can be applied to other operations. Inasmuch as drilling and blasting is only scheduled for a five-day week, two shifts per day, the manning calculations would of course take this reduced schedule into account.

Unavoidable Overtime: Usually an effort is made to avoid all overtime by scheduling individuals in such a manner that no person works more than 40 hours per week. However, it is almost impossible to avoid some overtime. For a small mine scheduled for six days per week operation, the labor would probably be paid for six days, and in the United States, this would amount to at least time and a half for the sixth day or weekly pay for 52 hours. The manning table should be based on sufficient labor to avoid overtime, but for the purposes of a feasibility study, 10% can be added to direct hourly wages as a line item for large mines and 15% or more for small mines.

Labor Burden: Labor burden means *fringe benefits*. Caution should be exercised when obtaining a factor for labor burden from existing operations. Such figures may contain items which, for a feasibility study, are covered elsewhere. In the example under consideration, sick leave, vacation, and holiday pay should not be a part of the labor burden because the employees are paid for holidays when the mine is not scheduled to operate and sick leave and vacations have been included in the calculation of the 1,872 hours per year that the average employee works. Overtime need not be in labor burden because it has already been accounted for as a line item on the manning table.

Labor burden usually consists of the following: 1) *Statutory Burden*: This includes items mandated by law, such as the employer's contribution to Social Security, Workmen's Compensation Insurance, Unemployment Insurance, and other costs that result from government action; 2) *Benevolent Labor Burden*: These are the items that an employer must pay to be competitive in the labor market to keep capable people. These include health insurance, group life insurance, pension plans, and other items directly related to wages and employment; 3) *Union Enforced Burden*: This includes items that may be the result of direct union negotiation.

Labor burden can be obtained from other operating companies and government agencies, but care should be exercised in identifying the included costs. As an approximation, true cash labor burden in the United States will be 25 to 35% of direct wages. However, it may be higher in some employee categories, and it can be higher in older operations that have many employees with many years of service. Overseas, it is not uncommon to find burdens of 50 to 100% or more. The best way to determine true cash labor burden is to make an actual investigation by contacting governmental authorities,

insurance companies, and whatever labor unions may be involved.

Manning the Operation: In Table 8 for the example under consideration, it will be noted that there are 12 supervisors for 126 employees and 12 clerical and engineering employees. There is one supervisor for each 9.5 employees. The ratio of operators to maintenance personnel is 1.68 to 1.0. This would be considered a good ratio; however in some operations, the ratio is one to one. A rough rule for feasibility studies is two operators to one maintenance employee.

More maintenance people will be required if on-site engine and transmission rebuilding is done and if tire shops capable of recapping tires are maintained. Older fleets of equipment may also require more maintenance personnel and the same is true if operation is scheduled for 100% of all time.

It is important when investigating operating mines to find out which people are classified as maintenance and which as operators.

In a feasibility study, the manning table need not be organized in a manner that distributes personnel by shift.

Table 8. Direct Operating Cost Supervision and Labor for a 14 Mt/a Open Pit Mine

	Number of People	Hours Paid	Hourly or Annual Wage \$	Annual Cost \$
Mine superintendent	1	Salary	50,000	\$ 50,000
General mine foreman	3	Salary	40,000	120,000
Drilling and blasting foreman	1	Salary	35,000	35,000
Shift foreman	3	Salary	35,000	105,000
Maintenance foreman	1	Salary	40,000	40,000
Maintenance shift foreman	3	Salary	30,000	90,000
Mining engineer—geologist	1	Salary	35,000	35,000
Planning engineer-surveyor	1	Salary	30,000	30,000
Draftsman-rodman	2	Salary	25,000	50,000
Exploration driller	1	2080	12.00	24,960
Drill helper	1	2080	9.00	18,720
Tim, Mtc, Supply clerks	3	2080	8.00	49,920
Secretary	1	2080	7.00	14,560
Messenger, sampler, truck driver	1	2080	7.00	14,560
Janitor	1	2080	6.00	12,480
Subtotal: Supervision	24			\$ 690,200
Blasthole drill operators	2	2080	11.00	45,760
Drill helpers	3	2080	9.00	56,160
Lead man blasting	1	2080	9.00	18,720
Blasters helpers	3	2080	8.00	49,920
Shovel operators	8	2080	12.00	199,680
Heavy equipment operators	12	2080	10.00	249,600
Truck drivers	35	2080	8.00	582,400
Subtotal: Operators	64			\$1,202,240
Electrician A	3	2080	12.00	74,880
Electrician B	3	2080	11.00	68,640
Mechanics A	8	2080	10.00	166,400
Mechanics B	8	2080	9.00	149,760
Field service men	4	2080	8.00	66,560
Maintenance labor	8	2080	7.00	116,480
Parts and tool room men	4	2080	8.00	66,560
Subtotal: Maintenance	38			709,280
Subtotal: Direct wages	126			\$2,601,280
Unavoidable overtime, 10% of hourly labor (operators & maintenance)				191,152
Burden, 30% of all wages				838,862
Total				\$3,631,734
Round to nearest \$1000				\$3,632,000

This is a matter which depends on experience and actual operations. It can generally be assumed that engineering and clerical help will work a 40 hour week on day shift. It can also be assumed that there will be more maintenance people on day shift than on the other two shifts. Drilling, blast hole loading, and blasting can probably be scheduled two shifts per day, five days a week. It is only important that the manning table have sufficient people. Only people operating production machinery should be distributed approximately equally on 3 shifts.

Machinery Operation: In Tables 2, 3, and 4 and the text that follows these tables, annual *costing* hours have been assigned. These are the hours of actual machinery operation that must be paid for. Table 9 provides calculations for determining the annual cost of mining machinery. Costing hours are multiplied by the hourly cost of the machinery exclusive of operating and maintenance labor.

It may be desirable to present a table that gives the hourly operating cost of each piece of mobile mining equipment by categories such as fuel, lubrication, engine supplies, tires, repair parts, and electrical power. In a mining feasibility study, such items as taxes, insurances, depreciation, and interest should not appear on this table because these items are more appropriately covered elsewhere, particularly in the section on economic analysis.

Details of operating costs are not always easy to obtain. The best source of information would be the records of an operating open pit mine that is similar to the mine being studied. Machinery manufacturers can frequently provide cost breakdowns. A word of caution is necessary concerning maintenance costs obtained from equipment manufacturers. These costs invariably include maintenance labor and in the example under consideration here this item is carried on the mining department manning table. It is therefore necessary to factor out maintenance labor cost from the maintenance figure provided by vendors. In the United States, labor is generally one-half to two-thirds of the maintenance cost and

the remainder would be parts; but in overseas situations, particularly where duty is charged on imported parts, the labor portion may be only 10 to 25%.

The table showing the breakdown of hourly cost for each machine, particularly on overseas jobs, can be quite valuable. It is a guide for logistics calculations because it provides information on parts and supply quantities to be transported and stored.

The hourly cost of machines in an open pit mine varies widely. Older fleets may cost more, and new fleets considerably less. The figures obtained from vendors are usually averages and should be adjusted, if necessary, employing judgment factors.

The annual cost of operating mining machinery is the result of costing hours multiplied by hourly operating cost with the aforementioned exclusions.

For small mines that do not have redundant equipment and for large mines that prefer to keep maintenance forces at a low level, a line item should be added to the machinery cost table for rental of equipment during major breakdowns and for off-site maintenance contracts. This is a judgment factor; but for small mines it could be as high as 25% of the total machinery operating cost, and for large mines it will be in the range of 10 to 15%. To a certain extent, this is a contingency factor.

Drilling Supplies: The hourly operating cost for blast hole drills is not intended to include drill bits. These are included in Table 10. The life of drill bits depends on numerous factors, most of which might not be known in a preliminary feasibility study. If air hole drilling with rotary drills or down-the-hole hammers have been used in the exploration program, some idea might be obtained about the possible bit consumption. Also, operating mines with similar ore and waste could be a source of such information. Vendors of drill bits can be a valuable source of information if first hand knowledge is not available from on-site drilling of the deposit or from similar mining operations.

Table 9. Annual Cost of Mobile Mining Machinery

Major Items of Machinery	Annual Costing Hours*	Cost per Hour† \$	Total Annual Cost‡ \$ × 1000
Blasthole drills, exclusive of bits	6150	75.00	461
Secondary drill rig	800	21.00	17
7.6 m ³ shovels	9915	115.00	1,140
77 t haulage trucks	45290	42.00	1,902
9 m ³ rubber tire front-end loader	2416	48.00	116
230 kw rubber tire bulldozer	10612	25.00	265
345 kw truck-mounted bulldozer	2400	41.00	98
Motor grader	2400	17.00	46
32 t small dump trucks	2400	21.00	50
Service vehicles, ANFO, fuel, repair	3800	12.00	46
Supervisors pickup trucks	10000	8.00	80
30 m ³ front-end loader	800	12.00	10
Subtotal	96958		\$4,226
Allowance for rental equipment 10%			422
Allowance for less than expected productivity, 10%			423
Total			\$5,071

* See Tables 2, 3, and 4 and text.

† Exclusive of operating and maintenance labor.

Direct operating cost, no ownership cost included

Information obtained mostly from vendors and represents averages. Costs should be updated.

‡ Rounded to nearest \$1000.

Table 10. Annual Cost of Drilling and Blasting Supplies

	Annual Cost \$ × 1000
Drill bits 97000 m ÷ 300 m/bit × \$4000/bit	1,293
Slurry 0.025 kg/t × \$1.43/kg × 12,700,000 t	454
ANFO 0.165 kg/t × \$0.804/kg × 12,700,000 t	1,684
Blasting cord 451000 m @ \$0.25/m	113
Boosters 1.0 kg/hole × 7028 hole × \$1.43/kg	10
Secondary blasting @ 8% of above total including bits	283
Total	\$3,837

Explosives: In Table 10, the cost of explosives is tabulated. This is a straightforward calculation and the most important information is the powder factor. From the powder factor and the annual tons to be blasted, the explosives cost can be determined. What the explosive mix will be is a matter of judgment and, again, an operating mine with similar ore and waste would be the best source of information. Manufacturers of explosives and the literature they publish are also good sources.

Undistributed Mining Department Overhead: This item is frequently overlooked. It is recommended that this be developed in some detail as shown in Table 11. The item is referred to as *undistributed* because it represents those costs

not directly assignable to labor burden, machine operation, or explosives. This item is most often forgotten by engineers who make operating cost estimates by the *unit cost* method. Usually unit costs are available for drilling and blasting, loading, hauling, etc., but none of these costs contain department overhead. A percentage factor can be applied for overhead, but it is risky and at times not very convincing.

Reliability of Estimates and Credibility Checks

Most mining engineers with some experience have certain credibility checks that they can apply to operating cost calculations. For example, in the United States, wages and burden should be about 40% (plus or minus 10%) of the

Table 11. Undistributed Mining Department Overhead

	Annual Cost \$
Mine office heat, 200 m ² @ \$30/m ² /yr	6,000
Electric power, 200 m ² @ \$30/m ² /yr	6,000
Telephone, 12 outlets @ \$300/yr/outlet, basic	3,600
Water and sewage, inside employees 12 @ \$50	600
Office supplies, \$300 yr, all staff employees, 24 × \$300	7,200
Engineering supplies, \$600 × 4 employees	2,400
Repair office and engineering equipment 24 employees × \$150	3,600
Safety and Training supplies 126 employees × \$50	6,300
Equipment usage during training 500 hr @ \$40 hr	20,000
Radio service 35 units @ \$150 yr/unit	5,300
Crew bus* 230 days × 105 km × \$1.24/km	30,000
Office building maintenance allowance 200 m ² × \$15.00/m ²	3,000
LD phone and telex allowance \$300/month × 12 mos	3,600
Professional cost†, 12 professionals @ \$1000/yr each	12,000
Exploration drilling, 1400 hr @ \$75/rig hour	105,000
Assaying \$1.0 per hole 7000 blastholes + 3000 Exploration boreholes @ \$10.00 each	100,000
Subtotal, Mine and Engineering offices	\$314,600
Heat, 1000 m ² @ \$22/m ² /yr‡	22,000
Electric power 1000 m ² @ \$35/m ² §	35,000
Telephone, 4 outlets @ \$300/yr/outlet	1,200
Water and sewage, 38 employees @ \$50/yr each	1,900
Small tool replacement allowance, 34 employees × \$300 yr	10,200
Undistributed maintenance supplies \$3.00 machine hour	291,000
Repair shop equipment \$300/employee, 34 employees	10,200
Shop building maintenance 1000 m ² @ \$10.00/m ²	10,000
Subtotal, Maintenance shop	381,500
Total	\$696,100

* Assume a subsidized crew bus and mileage cost covers depreciation, tax, insurance, etc.

† Publications and professional activity such as AIME.

‡ Lower heat level than office building.

§ Higher power use than office building.

Table 12. Summary of Direct Cost Mining Department

	Annual Cost \$ × 1000	Cost of Material Moved \$/t
Supervision, labor and burden	0.29	3,632
Mobile machinery	0.40	5,071
Drilling and blasting supplies	0.30	3,837
Undistributed overhead	0.05	696
Local taxes (non-income related) and insurance*	0.06	720
Total before contingency	\$1.10	13,956
Contingency†, 20%	0.22	2,791
Total	\$1.32	16,747
Annual Tons Material Moved: 12,700,000		

* Unless firm data is available, use 3% of total mining department capital cost which, in this example, would be about $\$24,000,000 \times 0.03 = \$720,000$.

† In this definition the percentage assigned to contingencies is a judgment factor and is not to be interpreted as meaning that estimates are necessarily accurate within this percentage range, nor is there an implied reference to any order of accuracy.

direct operating cost of an open pit mine. There are always special circumstances that would change this percentage. The direct operating cost of mining machinery will depend on such things as fuel, remoteness of the operation, etc., but it will amount to about 37% (plus or minus 10%) of the direct operating cost. Blasting supplies can vary widely. For explosives alone the percentage is 12 to 15% in most instances. Explosives can be very expensive overseas. Undistributed mining department overhead will vary widely, but it is about 10%. See Table 12.

Production in terms of total tons of material per man shift in the mining department is a good credibility check. Unless there are unusual circumstances or a very small mine is involved, less than 200 t of total material moved per man shift is unacceptable. The study should be reviewed for underestimation of machine capacity and too many employees. Two hundred to three hundred tons per man shift is in the acceptable range, 300 to 400 t is good, and 400 to 600 t is excellent and achievable in many operations. It is important

to note that this figure is based on total tons of material moved and this includes ore and waste, and the total number of employees in the mining department.

ECONOMIC ANALYSIS

Economic analysis is not very meaningful if the mine is a part of a larger integrated concentrating and smelting complex. If the mine sells raw ore with no beneficiation except primary crushing, then the mine becomes an economic unit generating revenue.

The details of discounted cash flow analysis, sensitivity analysis, and payout time are discussed later in this work. However, a simple *spot* cash flow analysis is frequently helpful. An example is given in Table 13. This procedure is used only to indicate whether or not a project is in the range of profitability. The analysis is for some *n*th year in the future when the project has reached design production and overcome initial start-up difficulties. Such an analysis assumes constant dollars. It can be used for preliminary comparison

Table 13. Spot Cash Flow Analysis for Preliminary Feasibility Studies*

	Annual \$ × 1000
Gross revenue 12.7 Mt @ \$2.64/t	33,528
Less direct operating cost 12.7 mt × \$1.32/t	16,764
Operating profit	21,336
Depreciation $\$24,000,000 \div 8$ years	-3,000
Interest @ 15% on 75% of investment, $0.15 \times .75 \times \$24,000,000$	-2,700
Depletion 15% of gross revenue† $0.15 \times \$33,528,000$	-5,029
Before tax profit	10,610
All income-related taxes, assume 50%	5,305
After tax profit	5,305
Add back depletion	5,029
Net profit	10,334
Add back depreciation	3,000
Cash flow‡	13,334
Payout time, $\$24,000,000 \div \$13,334,000 = 1.8$ years	
ROI $\$10,334,000 \div 24,000,000$	43%
ROE $\$10,334,000 \div 6,000,000$	172%

* Assume a mining contract delivering ore to the buyer's crusher from a deposit owned by the mining contractor. Assume all material moved is ore.

† Some foreign countries have no provision for depletion. See US tax laws on depletion.

‡ Assume no investment credit or tax holiday.

of alternates such as shovels and trucks vs. bucket wheel excavators and conveyors. More sophisticated programs are adapted to a computer program.

ECONOMIC VIABILITY-CASH FLOW ANALYSIS

Feasibility studies may have many different purposes. However, in many cases the final objective will be to serve as a reliable document to be presented to a lender. Therefore, the economic viability of the mining venture must be demonstrated in the feasibility study.

The main test of the overall economic viability, from a lender's point of view, is through cash flow analysis. "A cash flow forecast that extends at least through the life of the proposed loans—and preferably for some additional years—should be prepared under the costing and marketing assumptions justified elsewhere in the report." (Gibbs and Sroka, 1978.)

The final decision on alternate choices, either of different mining projects or changes in parameters, such as production rates, methods, etc., is based on a rational continuous process, namely economic analysis.

Principles of an Economic Model

In general, an economic model for investment decisions should consider four important principles as given by Haynes and Massie, 1969.

The Incremental Principle: A decision is sound if it increases revenue more than costs, or if it reduces costs more than revenue. This seems obvious; however, its application is not obvious at all, and using average costs as the basis for the decision model could lead to error, or at least it does not present a complete picture of the investment alternatives.

The Principle of Time Perspective: A decision should take into account both the short and long term effects on revenues and costs, giving appropriate weight to the most relevant time periods.

The Opportunity Cost Principle: Decision making involves a careful measurement of costs. The company must evaluate the opportunity cost of investing in the proposed project as compared to other investment possibilities (Joy, 1980).

The Discounting Principle: If a decision affects costs and revenues at future dates, it is necessary to discount these costs and revenues to present values before a valid comparison of alternatives is possible.

The four principles, previously mentioned, are the framework of economic analysis which will interrelate the areas of mineral resources, technology for recovering the resources, the annual capacity of the proposed mine operation, the capital investment required, the estimated operating costs, and the profitability criteria for the final investment decision.

In the final analysis, the evaluation of the profitability of the investment is measured by the difference between the summation of the present value of the expected proceeds over future years vs. the capital invested today. This could be simply expressed by $P. \text{ Value of Cash flow} = P. \text{ Value of Investment} + P. \text{ Value of Profit}$.

In summary the economic analysis in the feasibility study is performed by formulating a model which should include the following elements: 1) evaluation of the main variables; mineral reserves, production rates, recoveries, cost estimations, prices of the commodity, regulatory and environmental factors; 2) profitability criteria; 3) cash flow projection model; and 4) test of the cash flow model.

Evaluation of the Main Variables

Several major variables are involved in the economics models. These variables are classified either as Industry Stimulant Group, Economic Stimulant Group, or Regulatory Stimulant Group (Beasley and Pfeider, 1972; Pfeider, 1980).

The Industry Stimulant Group model contains: 1) mineral reserves, tonnage and grades (cut-off and average); 2) production rate and grade, corrected for dilution; 3) alternative mining, mineral processing, and metals recovery methods; 4) anticipated product recoveries in the mining, processing and metals recovery steps. And, for each of the above set of variables: 1) operating and overhead costs; 2) transportation and sales expenses; 3) capital costs for mine, plant and infrastructure; and 4) working capital requirements.

The Economic Stimulant Group model consists of: 1) market prices of products; 2) equity—loan ratios; and 3) interest rates and payback times of loans.

The Regulatory Stimulant Group model variables are: 1) depreciation and amortization rates; 2) depletion allowances, if any; 3) royalties and/or profit splits; 4) tax rates for ad valorem, property, production, profits, custom duties, transfer of dividends; and 5) tax moratoriums, investment credits.

Some of these variables have already been described in detail elsewhere in this chapter; however, they are repeated here with the objective of presenting an overall view of all the factors involved in the economic analysis.

While the Industry Stimulant Group has its impact in the design and estimating phase, the Economic Stimulant Group (market prices and loan arrangements) and the Regulatory Stimulant Group (representing taxing structures) are of equal or perhaps greater importance because the firm has only limited or no control over these variables.

In general, the main objective of the Economic Model is to estimate the annual return. However, in this process the projected return is dependent upon two types of parameters identified by Wells (1978) as "nondiscretionary and discretionary parameters." Discretionary parameters include mining and beneficiation methods, annual production capacity, sequence of mining, cut-off grade, design of the mine, processing plant, and facilities required to obtain an efficient production. Nondiscretionary parameters are those which the firm cannot control directly, such as selling price of the product, basic costs of labor and supplies, taxes, regulations, etc.

Profitability Criteria Used in the Evaluation

The criteria to be selected for the evaluation will depend on the investment objective of the parties concerned in the mining venture. Several profitability criteria are widely used by the mining industry, financial institutions, and government agencies to evaluate individual projects and to compare alternates between mutually exclusive mining ventures. There are two general groups of profitability criteria: 1) *Non-discounted cash flow*—payback period and average internal rate of return; 2) *Discounted cash flow*—Hoskold Formula, Net Present Value (NPV), Internal Rate of Return (IRR or ROR), Profitability Index (PI), Payback Period.

For evaluation purposes, the discounted cash flows are the only profitability criteria used, since the time value of money is the most important principle in the evaluation process. The following is a brief review of the profitability criterion of this group.

The Hoskold Formula has been used since 1877; however, its use is limited today. It calculates present value by discounting future annual income at a risk rate while building

a sinking fund to repay investment at a safe rate. The present value (PV) is calculated by the following formula:

$$PV = \frac{A}{\frac{r}{(R^n - 1)} + r^1}$$

where PV is present value, A is annuity (annual cash flow), r is safe discount rate, r^1 is risk rate, n is number of years, R is $(1 + r)$.

Net Present Value (NPV) has been widely used since the 1960s. It calculates net present value by discounting estimated annual cash flows to a common point of time at a selected discount rate considering the risk of the investment.

$$\text{Net present value (NPV)} = \sum_{t=0}^N \frac{\text{Cash Flow (CF)}}{(1 + k)^t}$$

where k is discount rate, t is number of years.

Internal Rate of Return (IRR) or (ROR) is the calculated rate that makes the present value of cash inflow equal to that of cash outlays, or

$$\text{Internal rate of return (IRR)} = \sum_{t=0}^N \frac{\text{Cash Flow (CF)}}{(1 + IRR)^t} = 0$$

where t is number of years.

Profitability Index (PI) is defined as the present value of future cash flow divided by the initial investment. This criterion is also called the benefit-cost ratio and is used in the capital rationing situation. This is the situation where a budget constraint is imposed, and the firm may not invest in all acceptable projects.

$$\text{Profitability Index (PI)} = \frac{\sum_{t=1}^N \frac{\text{Cash Flow (CF)}}{(1 + k)^t}}{\text{Original Investment}}$$

where k is discount rate, t is number of years.

Payback Period represents the number of years required in the cash flow analysis for the accumulated cash flow to equal investments. This is measured either from the initiation of the project or from the start of the operations. This criterion is especially useful for mining ventures with high risk or short life. Normally the payback period is expected to be one to three years for high risk projects, and six to ten years for low risk projects.

The selection of the criterion for the evaluation of the mining property will depend upon the criteria best suited for the investment objective. However, there is a trend to use the present value and rate of return techniques for economic analysis. These techniques, in conjunction with sensitivity and risk analysis, are good analytical tools for simulating the impact of the uncertainty on the profitability measurement, either present value or rate of return. These simulation techniques will be treated in more detail later in this section.

Rate of Return Vs. Present Value

The Internal Rate of Return (IRR or ROR) is easy to understand because it has intuitive economic meaning. It works well on simple accept/reject problems but its main drawback could be that it may not give the best selection criteria for complex accept/reject problems (multiple rates), mutually exclusive of choices and capital rationing.

The Net Present Value (NPV) is relatively easy to calculate. It is considered by many people as the best method for mutually exclusive ranking problems and for accept/reject decisions. Its main disadvantages could be that some-

times it is not easy to understand the concept and it may not work well for capital rationing situations. In the latter case, the profitability index (PI) works better than net present value (NPV).

Probably the most troublesome part of the net present value calculation is the estimation of the discount rate, which will convert the cash flows projected to the net present value at a given point in time.

Various financial treatises give details for estimating the discount rate; however, in this section, the authors provide an overview of one method for estimating the discount rate using the equation known as *Capital Asset Pricing Model*, *CAPM* (Joy, 1980).

The interest rate or discount rate (K_x) may be estimated by the following linear equation.

$$K_x = K_{rf} + (K_m - K_{rf}) \text{Beta}_x$$

where K_x is the interest rate required for X investment, K_{rf} is the risk-free interest rate, K_m is the interest rate at market value, Beta_x is the investment risk for X investment. "In principle, K_{rf} is observable in the market place and K_m can be estimated. The interest rate for US Bonds is usually taken as a basis to estimate the risk-free rate (K_{rf}) for long term investments."

"The most common method of estimating Beta_x is by regression analysis. Rates of return on the firm's stock, R_e , and rates of return on a market index, R_m values are statistically related by the straight-line equation called market model." (Joy, 1980.)

$$R_e = a + \text{Beta}_x R_m$$

About five years of monthly rate of return are used to estimate Beta_x . Further discussion of this model is beyond the scope of this work. Nevertheless, to complete our overview, we add the following values: 1) For a risk-free investment, $\text{Beta}_x = 0$; 2) For $K_x = K_m$, $\text{Beta}_x = 1$. 3) For $K_x = 1.4 K_m$, $\text{Beta}_x = 2$.

Cash Flow Model

Financial treatises give several reasons for using cash flow in the evaluation of investment alternatives. The three main reasons for using cash flow in the evaluation of mining investment are summarized as follows: 1) Cash flow yields a better measurement of the net economic benefit associated with the mining venture; 2) Cash flow avoids accounting ambiguities; 3) Mining companies are permitted depletion allowances in addition to the depreciation allowances. These noncash expenditures are tax deduction items that are added back into the cash flow stream.

The cash flow after tax stream consists of four main parts:

$$\text{Net Cash Flow} = A - B + C - D$$

where A is gross income, B is cost deductions, C is noncash expenditure, D is capital expenditure. A typical format for estimating annual cash flow is presented in Table 13a.

Test of the Cash Flow Model Evaluation

In the evaluation of a mining project, we consider three basic elements for discriminating between alternatives. These elements are: 1) project cash flow estimations; 2) appropriate discount rate; and 3) profitability criteria for the decision making process consistent with the objectives of the firm.

Regardless of the methodology used to develop the estimate of the profitability of the project, the fact is that the result is subject to a level of uncertainty. This level will depend upon the degree of reliability of each of the variables involved in the calculation. The uncertainty is due to the

* If any deduction is applicable.

fact that the projections of future cash flows as predicted by the model, are only at best, *good estimates*. These estimates are obtained from data and conditions as known at the time of the model formulation.

In order to evaluate the effect of changes in values of variables incorporated in the model on the profitability criteria, two techniques are generally used. One is the simulation using the *Monte Carlo* technique or risk analysis simulation, and the other is *sensitivity analysis*. With the advent of the computer and rapid simulation programs, there is an increasing application of these techniques.

Sensitivity Analysis: Sensitivity analysis varies the range of a single variable at a time. The procedure is repeated for the other variables. In this fashion the most sensitive parameters of the model are detected. The process for testing the sensitivity of the model consists of changing one variable and holding constant the others at their estimated most likely value. The variation for the single value will range from its minimum to its maximum estimated value. The effect, in either present value or rate of return, is recorded in a matrix form with the main parameters and their respective changes in values.

Simulation Using Risk Analysis: Risk analysis* is a systematic analysis of the risk associated with various dependent

variables to develop a final expected distribution of the profitability measurement. This distribution is used for the decision making process of the investment alternative.

This technique is also known as *Probabilistic Analysis*. It simulates numerous variations in the range of all the main variables at the same time. The simulation is carried out by computer programs using randomly selected values from given statistical distributions.

This approach is widely used today. Its general application in evaluation of projects was originally proposed by D.B. Hertz in 1964. The main feature of the technique is that it gives the decision makers a schedule indicating the frequency distribution of the profitability criteria and their respective relative probability of occurrence. At the same time, it will indicate if the investment has any chance of being a total loss.

When the feasibility study is performed with the objective of selecting a mining venture between various alternate investments, risk analysis is a powerful analytical tool for identifying in a realistic way the alternate that offers the greater economic comparative advantage in line with the objectives of the firm.

Often, the alternates differ in location, tonnage and grade distribution, size of equipment, operating costs, life of op-

eration and equipment, etc. The main factors for discriminating between these types of alternatives are the estimation of capital and operating costs. These costs are deterministic events by the nature of their development.

The cost estimation of a new mining venture, regardless of the detail contained in the estimates, is subject to a level of uncertainty. This uncertainty is, in fact, a pervasive feature of the cost estimating process because of the lack of complete knowledge about the conditions or efficiency of the future operation. A search in the technical literature shows that there are several good descriptions of the risk analysis method.

The main concept and elements are summarized here to present a comprehensive overview of the analysis. It is hoped that the description will give the reader some insight for practical applications of this technique for the evaluation of mineral deposits or other selection of alternatives in the mineral industry.

Type of Risk in Mine Evaluations

Risk is inherent in the decision to invest capital for converting mineral resources into future expected profit or, simply stated, in mining jargon, there is always a risk in the process of converting mineral resources into ore.

There are two types of risk in mine evaluations: 1) risk inherent to the physical characteristics of the mineral body, and 2) risk associated with future events.

Risk Inherent to the Physical Characteristics of the Mineral Body: The mineral reserves obtained from the geologic model contain a level of uncertainty, depending upon the amount of exploration data used as a basis for the model. This is due to the fact that the reserves estimation is based upon a small, physically known fraction of the mineral body. Therefore, the tonnage and grade of the entire deposit are inferred from a relatively small sample. Consequently, the specific mineral content, based on the information available at the time of the study, is limited by the sample population and the geometry of the mineral body.

The advent of geostatistics permits us to greatly reduce this uncertainty. Geostatistics reveals a great deal about the idiosyncrasies of mineral distribution and its spatial location. Consequently, the reliability of the in situ reserves estimations are considerably improved. It should be emphasized that by far the most important factors in the reliability of the reserves estimates are good core recoveries, good sampling, and good assaying procedures. It would be a fallacy to use a sophisticated geostatistical model with questionable data base. Therefore, in a complete feasibility study, it is essential to review the sampling procedures and confirm the reported assays.

The expected mill head grade will depend upon the grade distribution of the deposit, the economic constraints imposed to define the limit of the ore body, and the proposed mining plan. However, this grade will be subject to variation due to dilution as a consequence of the following factors: geometry of the ore body, mining practice and unknown geological factors at the time of the study.

Risk Associated with Future Events: In general, a mineral deposit takes three to seven years to bring into production after the firm has made the investment decision. Depending upon reserves, it will take another 10 to 30 years to exploit the ore body considered in the evaluation. During this period many events could happen that will affect the following parameters: price of the commodity, initial and replacement capital costs, operating cost, taxation policies, and change in government policies regarding partial or total

ownership of the mineral properties. In the life of the properties, including the development period, there is the possibility that all the main parameters involved in the evaluation could deviate from the original estimates. Several combinations of variations in parameters could occur and these variations will affect the profitability estimate of the property under evaluation.

Procedure for Simulation by Risk Analysis

The process of performing a systematic risk analysis for the measurement of profit associated with changes of the main dependent variables consists of three main elements: 1) estimation of the basic values of the main variables; 2) estimation of the probability of occurrence of each estimated value; and 3) selection, at random, of one value from the probability distribution for each variable. The general methodology to be used is illustrated in Fig. 2.

Estimates of the Basic Values of the Main Variables:

Up to this point, the basic values of the main variables have been established with the formulation of the geological model (including cut-off grade, average grade, and tonnage), revenue forecast, and the development of capital and operating costs. A typical schedule of the basic values of the main variables is as follows:

1. Total tonnage at given cutoff grade, number of tons.
2. Average in situ grade, percent.
3. Dilution, percent.
4. Average mill head grade, percent.
5. Annual mining rate, number of tons.
6. Metallurgical recovery, percent.
7. Estimated annual revenue, dollars.
8. Estimated capital costs, dollars.
9. Estimated operating costs, dollars.

Estimates of the Probability of Occurrence of Each Basic

Value: The estimation of the probability of occurrence of each basic value is the step that is most likely to trouble the mine evaluators. However, there are three general ways of approaching the estimation: 1) mathematical probability, 2) inferred probability, and 3) subjective probability.

Mathematical Probability—is the generation of stochastic variates for several distributions, such as normal, uniform, binomial, and is easily manipulated by a computer program. Naylor, et al., (1966) provide formulas and programs for generating the probability distribution.

Inferred Probability—by fitting curves has been suggested by Harris (1970) when there is historical or other data available and when the probability distribution law is unknown. He suggests that, "The estimate be made by the fitting of a polynomial of some unspecified degree to the data or the grouping of data into class intervals, and then calculating the relative frequencies for each class."

Subjective Probabilities—are typically cases where there are components for which there is no historical information applicable for the fitting of a probability distribution. The estimation of capital and operating costs are some of these components. A general procedure for forming a subjective probability distribution is given in the following section.

The estimation of the average value of each component is expanded to represent the possible range of variation of the basic values and the likelihood that these values will be reached. The range could be estimated with some degree of confidence by experienced engineers involved in developing the basic values of the cost components of the feasibility study. The degree of confidence is directly related to the

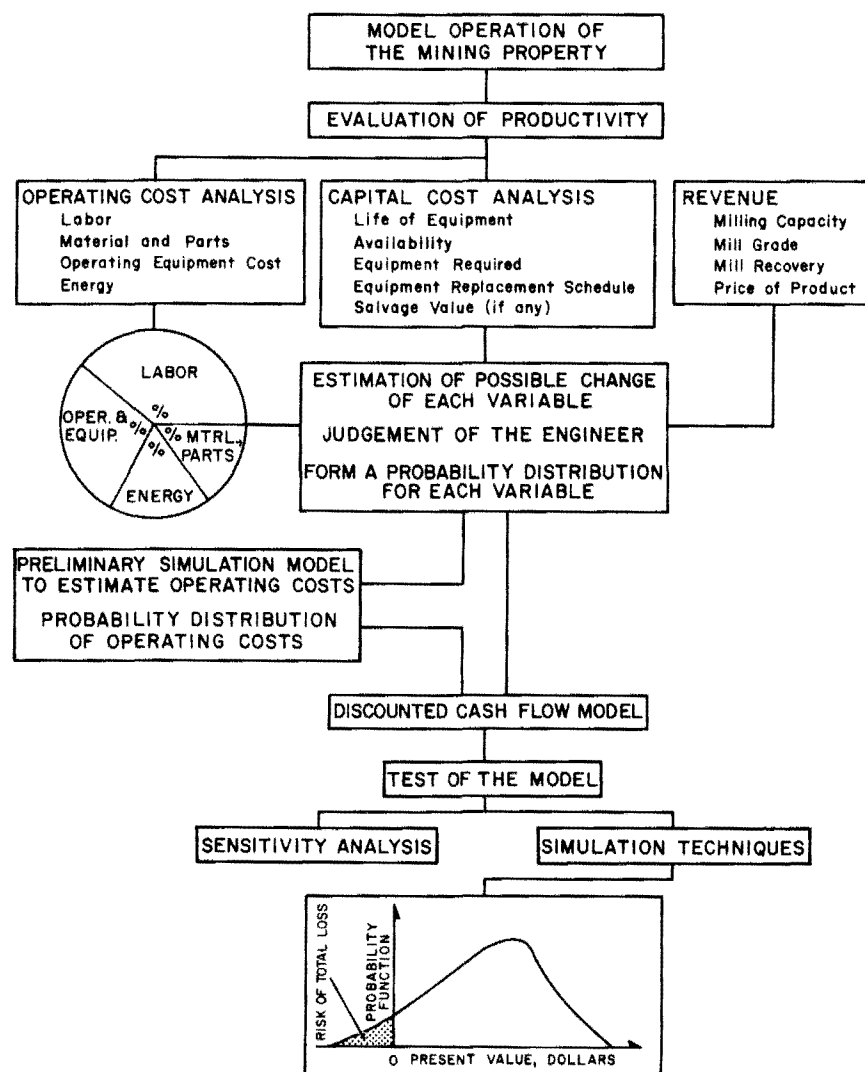

Fig. 2. Logic diagram for a risk analysis applied to a mine feasibility study.

amount of detail contained in the estimates and judgment from the experts.

Procedure for Forming a Subjective Probability Distribution Curve

Probability distribution, in general, is an idealization of the way certain events, or intervals, might occur. Subjective probability, in particular, quantifies the judgments from experts with respect to the particular range and pattern that their predictions may form.

In the estimation of the costs of new mines, experienced engineers involved in developing these estimates have a good idea of the degree of confidence they have in their estimate. This confidence is directly related to the amount of detail involved in developing the cost of the average estimated values. The greater the confidence in the estimate, the less will be the possible value range about the given estimate number. Conversely, the less the confidence, the greater the possible value range.

The sequence to follow in the process of forming a subjective probability distribution of possible cost values is: 1) identify the main cost components; 2) express the degree of confidence for the range of values of each estimated com-

ponent cost; 3) compute the weighted average degree of confidence for the total of all estimated costs; and 4) compute the range of values and their respective degree of confidence.

Two general cases are possible for forming the subjective probability distribution of values: 1) symmetrical distribution, and 2) skewed distribution.

Symmetrical distribution occurs when the engineer believes that the mean of the estimated value (U) might vary in an amount (d) on either side of the true value. The possible range of values for this case would be:

$$X = U + d$$

$$d = X - U.$$

In this case, the distribution curve is symmetrical and the *standardized score* approach is applicable in forming the probability distribution. If X is considered a value of a random variable, then the corresponding standardized score, relative to the probability distribution is $Z = \frac{X - U}{\sigma}$. "The Z score tells how many standard deviations (σ) away from the mean (U) is X ." (Hays 1963.) In other words, the stan-

standardized score is a deviation from expectation relative to the standard deviation.

Skewed distribution is the case when the engineer estimates that the mean value (U) will vary in a nonsymmetric way, generally described as skewed. In this case, the length of the tails of the distribution relative to the central section are not equal. When the deviation (d_1) is furthest to the right, the curve is *skewed positively*. When the deviation (d_2) is furthest to the left, the curve is *skewed negatively*.

In describing the skewness of a distribution in terms of measures of central tendency, we should recall the contrast between mean and median. Mean (M) is the point where the sum of deviations about the mean is zero. Median (Mo) is the point at which exactly 50% of the events fall. In general, for a symmetrical curve, M equals Mo ; for a positively skewed curve M is less than Mo ; and, for a negatively skewed curve M is larger than Mo . The standardized score with some modification can also be applied to a skewed curve of probability distribution. However, a triangular distribution seems to be more adequate to infer the intermedian points of this type of distribution.

Example of Inferring a Subjective Probability Distribution

The following example illustrates the procedure for quantifying a subjective probability distribution.

The estimated annual mining operating cost for a new open pit mine is \$21,600,000. The mine will produce 12 Mt of ore per year. The mine operating cost is then \$1.80/t.

Identification of the Main Cost Components: The main cost components are:

	% of Total	Cost per Components, \$
Labor	43	0.77
Equipment	30	0.54
Material	20	0.36
Energy	7	0.13
Total	100	1.80

Degree of Confidence: Based on the details involved in the performance evaluation of the equipment, the labor productivity and other economic factors, the engineers feel the basic amount of each cost component will not vary more than plus or minus 20%. However, they feel that due to the more known factors in some components than others, the degree of confidence for each cost component is as follows:

	Degree of Confidence %
Labor	90
Material	85
Equipment	85
Energy	65

Weighted Average Degree of Confidence: An illustration of the computation of the related cost components is given as follows:

Components	% of Total	Cost Component, \$	Confidence Level	Product
Labor	43	0.77	90	69.30
Material	30	0.54	80	43.20
Equipment	20	0.36	85	30.60
Energy	7	0.13	65	8.45
Total	100	1.80	84	151.55

The range of variation (d) for the estimated mining operating cost, and symmetrical probability distribution with a degree of confidence of 84% will be:

$$X = 1.80 \pm 0.20 \times 1.80 = 1.44 \text{ to } 2.16$$

Probability Distribution: Case 1. Assume a normal symmetrical distribution curve. U equals 1.80 of the average estimated cost, X equals 2.16 maximum cost at 84% of confidence level. Using the standardized score, we have

$$Z = \frac{X - U}{\sigma}$$

The degree of confidence of 84% refers to the subjective probability that the average estimate will deviate from the expected value relative to the standard deviation. The 84% is expressed as $F(Z) = 0.84$.

From a cumulative normal probability table, we find that for $F(Z) = 0.84$; $Z = 1$. By substituting Z in the standardized score equation, we obtain the corresponding standard deviation as follows:

$$\sigma = \frac{X - U}{Z} = \frac{2.16 - 1.80}{1} = 0.36$$

By changing the value of the variable X and keeping the standard deviation constant, we develop the frequency of distribution for the intervals of $(X - U)$. Since the given intervals are in fact mutually exclusive events, the sum of the frequency distribution or probability distribution of occurrences must be equal to 1.0 or 100%.

An example of the probability distribution computation is summarized in Table 14.

Nonsymmetrical Distribution: Case 2. For the purpose of illustration, a positively skewed curve in which most of the values are expected to fall in the higher range of costs, will be used. Calculations for Case 2, as in Case 1, will use the following criteria: 1) average estimated cost, \$1.80; 2) degree of confidence (weighted average), 84%.

However, unlike Case 1, in the opinion of the engineer, the cost will vary within the following limits: \$1.62 to \$2.34 (degree of confidence, as above). Overall, the cost will not fall under \$1.50 or exceed \$3.30.

The foregoing criteria yield a triangular distribution that simply reflects the judgment of the engineer in that a value close to the estimated average (\$1.80/t) is assigned a higher probability of occurrence than a value further from the estimated average. For practical purposes, it is assumed that the probability of occurrence of the intermediate values vary linearly, with respect to the probability of occurrence of the best estimated average. By solving for the area percent relationship of the triangles shown in Fig. 3, and estimating the probability of occurrences of the intermedian values, the subjective probability distribution is quantified as shown in Table 15. This type of distribution can also be obtained by using mathematical expressions for both positively and negatively skewed curves as given by O'Hara (1982). However, since the original data base reflects only the subjective decisions of the engineer, a simple approach is adequate at this point.

Simulation of Values from Probability Distributions

This simulation is the last step in the process of performing a risk analysis evaluation. This is the easiest and fastest operation in the analysis because it can be performed by a computer program.

The most common procedure for simulation is the *Monte Carlo* technique which is the process of randomly sampling values of the main variables contained in the analysis from a probability distribution. The simulation involves the generation of random values for each variable, the computation of the profitability measures, and the repetition of the process many times (100 to 1,000) until enough values are obtained to construct the overall probability of occurrences of the profitability measures.

The simulation produced by the computer can also provide the distribution curve. Therefore, it is an operation that frees the engineer from having to run the analysis and it takes only a few minutes to perform.

Almost all the published technical papers on risk analysis are predicated on the *Monte Carlo* simulation. However, there is a new technique developed by O'Hara (1982), "The procedure is based on the mathematical relationships of the skewed curve to determine the incremental variations in the estimated value of each element parameter."

The O'Hara approach is called *Root Sum of Squares (R.S.S.)*. The distinct feature of this technique is that it allows for the interrelationship of parameter variation when pairs of parameters are judged to be compensative or additive in their joint effect on the profitability measure. Typical additive situations are ore reserves vs. mill grade, mill recovery vs. grade of concentrates.

The evaluation of the advantages and disadvantages of the *Monte Carlo* vs. *Root Sum of Squares* techniques with regard to their application to risk analysis is beyond the scope of this chapter.

Case Study of A Simulation Using Risk Analysis

Basic Criteria and Assumptions: A hypothetical 12,700,000 overall tons per year mining operation in the western United States shall be used as a case study. The following assumptions are made: 1) The deposit is within

reasonable distance of a small population center; 2) Out of the total tonnage mined, a production level of 10 Mt/a of copper ore is expected; 3) Average copper grade is 0.87% with no byproducts; 4) Metallurgical recovery is 87%. 5) The waste-to-ore stripping ratio is 0.27:1.

Because of the relatively small scale of the hypothetical operation, no smelting and refining capability is considered and it is assumed that the concentrates will be shipped to a smelter for tolling.

The capital costs include the following items: 1) land, environmental, exploration, and metallurgical testing costs; 2) preproduction stripping; 3) mining equipment including freight and erection; 4) civil work, site preparation, and plant site access, including construction of a power line; and 5) cost of construction, including wages, payroll additives, consumables, materials, equipment usage, service, engineering, procurement, management costs and fees.

The operating costs are estimated for a situation in which the mine and plants are in operation in mid-1982. These costs specifically include wages, salaries, burden, costs for fuel and electrical power, spare parts, and operating supplies.

The basic criteria and assumptions for the model operation are summarized in Table 16.

Present Value and Rate of Return of the Cash Flow Projection of the Base Case: In performing a mine evaluation, the usual procedure is to determine either the present value of the property or the value of the funds which if invested at a given interest rate would return the same income flow.

In order to produce the evaluation, the cash flow plan should be developed in line with the criteria and assumptions summarized in Table 16. The cash flow projection for the estimated average basic conditions is illustrated in Table 17.

From the net cash flow plan given in Table 17, the present value and rate of return of the investment are calculated. This calculation shows a net present value of \$71,750,590 and an internal rate of return of 20.9%.

Sensitivity Test: As discussed in the section under Sensitivity Analysis, the model may be sensitive to changes in the variables. This model, for instance, is very sensitive to

Table 16. Basic Criteria and Assumption for the Economic Analysis Case Study

1. Initial Investment	
a) Capital already invested—land, exploration, studies, met. tests	\$17,000,000
b) Plant construction and equipment to be expended in 3 years as follows:	
Year 1 (ending 1984)	42,500,000
Year 2 (ending 1985)	54,700,000
Year 3 (ending 1986)	54,800,000
	<hr/>
	\$152,000,000
2. Replacements Cost	
Year 7	\$6,000,000
3. Life of the Operation	12 years
4. Depreciation	
Straight line method over an average life of 12 years	S/L
5. Depletion Allowance	
50% of net income	
6. Operating Costs	
Mining including primary crushing	18,000,000
Concentration	36,000,000
Transportation of concentrates	6,400,000
Total	<hr/>
	\$60,400,000
7. Working Capital	
Estimated @ 3 months of operation (0.25 × 60,400,000)	\$15,100,000
8. Annual Production Capacity	
a) <i>Design capacity</i>	10,000,000 tons of ore
@ Av grade of 0.87% Cu	
production of concentrate of 28% Cu	= 270,320 tons of concentrate
b) <i>Start-up</i>	
First year (end 1984): 50% of capacity	= 135,160 tons of concentrate
Thereafter	270,320 tons of concentrate
9. Revenue	
Copper concentrates @ \$480/t.	
At design capacity, annual revenue	\$129,754,000
10. Financing	
The purpose of the evaluation is to discriminate between alternative investments; therefore, all investment is assumed to be from equity for all practical purposes.	
11. Escalation	
No escalation is applied	
12. Profitability Measure	
Since it has been assumed that the evaluation is aimed toward selection between mutually exclusive alternatives, the present value of the discounted cash flow will be used as the profitability criterion.	
13. Discount Rate	
The discount rate or interest rate is estimated as follows:	
$K_x = K_r + (K_m - K_r) \text{Beta}_x$	
K_r = risk-free interest rate, 10%	
K_m = interest rate at market value, 15%	
Beta_x = investment risk = 0.80	
$K_x = 10 + (15 - 10)0.8 = 14\%$	
14. Salvage Value	
Equipment	\$13,700,000
Working capital	15,100,000
Total	<hr/>
	\$28,800,000

Table 17. Net Cash Flow Projection of the Base Case Operation (\$ × 1000)

change in revenue brought about by a change in either the grade of ore or the price of the product.

The profitability measures illustrated in Table 19 are obtained by simulating various mill head grades and keeping constant all other parameters. Similarly, if only the price of the ton of concentrate changes in the same percentage, the values of the profitability measures will change as shown in Table 18.

The grade and price are typical parameter pairs that are compensative or additive in their joint effect on the profitability measure. Therefore, a change in revenue could be due to the joint effect of the variability of certain parameter pairs, for example, grade to the mill and price of the product.

Test of the Model Under Uncertainty: There are many

possible combinations of the main variables that would yield a present value of \$71.75 million or 20.9% rate of return. However, at this point, we do not know what the probability is that these profitability measures or another value, either higher or lower, can occur. Therefore, it will be necessary to simulate various combinations of changes in the values of the main variables. In this way, it is possible to evaluate the effect of these changes on the profitability measure and determine the frequency of occurrence of either the required present value or rate of return.

The simulation is performed following the general procedure described in the section under "Procedure for the Simulation by Risk Analysis," which consists of the following three main elements: 1) estimates of the basic values of the

main variables; 2) estimates of the probability of occurrence of each assumed value; and 3) simulation technique involving selection at random of one value from the probability distribution for each variable.

Values of the Main Variables: The main variables are established in the basic criteria and assumptions for the case study given in Table 1. However, it is emphasized that some variables have joint effect (such as annual production rate, grade to the mill or price of the commodity) on the annual revenue which could result from either additive or compensatory effect. In this context there are only three main variables and their values are: 1) revenue at full production, \$129,754,000; 2) capital expenditure present value at the beginning of year one of operation, \$196,526,000; 3) operating cost at full production, \$60,400,000.

Probability Distribution of the Main Variables: Following the procedure described in the sections under "Procedure for Forming a Subjective Probability Distribution Curve" and "Example of Inferring a Subjective Probability Distribution," the probability distributions for the three main variables were formulated. Tables 19, 20, and 21 give the probability distributions of the revenue, capital cost, and operating cost intervals, respectively.

Simulation Technique: The simulation involves selecting at random, by computer, one value from the probability distribution of each variable. The combination of these values is then used to calculate the present value of the cash flow of the operation. This process is repeated many times to form a probability distribution curve of the present values.

Evaluation of the Simulation Model: The present values of the cash flow and their respective frequencies of occurrences obtained by the simulation process are tabulated in Table 22. The values shown on this table are used to form the risk profile of the feasibility study depicted in Fig. 4.

From Fig. 4 the following conclusions can be drawn:

1) The most likely range of the present value is \$62.6 to \$77.4 million at a confidence level of 95%. There is a 50% probability that the value will fall below this range, and a 37% probability that the value will exceed this range.

2) The property has a 35% probability of not attaining the minimum present value required to cover at least a rate of return of 14%.

3) The property has a 5% probability of being a total loss.

It is hoped that this systematic approach to the evaluation of a surface mining property will provide support to those readers involved in mine feasibility studies.

4.3 Financial Analysis

LOIS L. BRAZDA

H. ANDREW THORNBURG

INTRODUCTION

The high risk and large capital expenditures that are characteristic of the mineral industry have made financial analysis one of the crucial elements in the resource development process. As with any business endeavor, the object is to provide a satisfactory return to the owners of the enterprise, whether they be public or private, consistent with the objectives of the enterprise. This section describes how criteria for financial analysis are established, presents methods of evaluating investment, and discusses areas of particular concern such as risk analysis, taxes, and corporate objectives. An attempt has been made to make the presentation universal, but in specific areas such as accounting and taxes more emphasis has been placed on United States practice. The Appendices contain examples of both.

Preceding sections of this chapter have described the various stages of feasibility studies and planning that are needed to gather the data required for evaluation of a project. From a financial analysis standpoint, the principal characteristics that set the mineral industry apart from others are the depleting nature of the resource itself and the very long project cycles. The financial cycle of a typical mining project is shown in Fig. 1.

To prepare an evaluation, criteria must first be established to assess the flow of funds over the project cycles and then a rigorous framework for measuring the performance of a project must be established.

Time Value Concepts

In a free market economy the time value of money or interest rate concept lies at the heart of all financial transactions. To properly evaluate the mineral investments with their long project lives, it is essential to have a methodology for evaluating past, present, and future cash flows.

Interest is the equivalent of rent paid for the use of money. Therefore, money borrowed today must be compounded at the appropriate interest rate to repay the principal and the rent due at some future date. The mathematical relationship for a Future Value (*FV*) given a Present Value (*PV*) or principal amount borrowed or invested for *N* periods at an interest rate (*i*) is:

$$FV = PV (1 + i)^N$$

For example: *PV* = \$1, Interest = 20% per period (*i* = 0.2), *N* = 3 periods

$$FV = (\$1) (1 + 0.2) (1 + 0.2) (1 + 0.2) = \$1.728$$

Conversely a future value that includes rent must be discounted to find the present value. The corresponding formula is:

$$PV = \frac{FV}{(1 + i)^N}$$

It is important to distinguish how interest is compounded in the project evaluation so results are comparable and un-

Fig. 1. Typical mining project cash flow.

Fig. 2. Compound growth.

derstandable by all concerned. Simple compounding is expressed in terms of the annual percentage rate of interest (APR for those familiar with US lending terminology). In the above example the APR was 20%. If interest was compounded quarterly, instead of annually, as is often the case with models utilizing corporate financial data, the quarterly rate that would yield the same result is not $20/4$ or 5% but 4.6635% as shown from the following:

$$FV = (\$1) (1 + 0.046635)^4 = 1.28$$

The effective rate or APR is still 20%, but in terms of a quarterly evaluation model the annual rate or nominal rate (number periods in a year times the interest rate for the period) would be referred to as 18.654%. The mathematical limit to the continuous compounding power series of $(1 + i) (1 + i) \dots$ can be expressed as:

$$FV = PVe^{iN}$$

The continuous compounding interest rate that satisfies the example is a nominal rate of 18.232%, a difference from

the effective (APR) rate of 1.768%, yet the results over the three-year period are identical. It is clear, especially at higher interest rates, that the financial analyst should be specific as to the basis used for an evaluation. It is suggested the results be expressed in terms of the effective annual rate no matter what nominal rate is used.

The financial implications of both compounding (Fig. 2) and discounting (Fig. 3) become increasingly pronounced as rates increase due to the geometric nature of the compounding process. Table 1 illustrates the striking effect after ten years of annual compounding. Over 10 years the difference in future values between 5% and 30% is not six times but 8.46 times. Starting with the same investment at year 0, it only takes 1.86 years at a 30% rate to reach the future value attained over 10 years at a 5% rate (5.37 times as long).

When considering the evaluation methods presented later in this section, it is important to remember the reverse implications of discounting. A dollar earned ten years from now is worth \$0.614 today at a 5% rate, while at 30% it is only worth \$0.118 (19.2% of the value at a discount rate of

Fig. 3. Discounted values.

Table 1. Examples of Compounding and Discounting

	% Per Annum					
	5	10	15	20	25	30
Future Value in 10 Years (\$1 invested today)	1.629	2.594	4.046	6.192	9.313	13.786
Present Value (\$1 earned in year 10)	0.614	0.386	0.247	0.162	0.107	0.073
Years to Future Value of \$1.629 (\$1 invested today)	10.000	5.119	3.491	2.676	2.186	1.860
Present Value of \$1.629 (earned in year 10)	1.000	0.628	0.403	0.263	0.175	0.118

5%). Higher interest rates in discounted cash flow analyses place rapidly diminishing values on future cash flows. As will be shown later, this generally discourages investments with the long lead times characteristic of the mining industry.

Establishing a Discount Rate

There is a general agreement in the mining industry regarding the need to recognize the time value of money in financial evaluations, but the selection of the appropriate rate to use is the subject of much disagreement, and with good reason. A government entity considering an investment might select the interest rate paid on government bonds, under noninflationary conditions, with a maturity matched to that of the project. To this rate, which in the United States has historically been in the range of 2%, a premium may be added if the project's risk is considered to be substantially different from projects normally undertaken by the government, and it must also be adjusted for inflation.

The analysis for a shareholder-owned firm with publicly traded stock contains the same basic elements but is much more complex. The primary objective of the firm is the maximization of the wealth of the shareholders over time. The shareholders benefit from the success of the firm through the receipt of dividends and the appreciation of the market price of the shares of common stock.

It is not possible to fully explore all the financial theory underlying the determination of the cost of capital to a firm. However, let us assume the cost of capital to a firm is primarily a function of the following:

$$\text{cost of capital} = (E) \times (D + G) + (1 - E) \times (1 - T) \times (I)$$

where E = equity as fraction of total capital
 = equity/(debt + equity)
 D = dividend rate
 G = growth rate in equity
 T = corporate tax rate
 I = before-tax interest rate on debt

An example of the application of this formula is:

Equity = 70%
 Debt = 30%
 Dividend rate = 5%
 Equity growth rate = 7%
 Interest rate = 12%
 Tax rate = 50%
 Cost of capital = $0.7(5 + 7) + 0.3(1 - 0.5)(12)$
 = $8.4 + 1.8$
 = 10.2%

For those requiring a more rigorous discussion, a number of books cover the topic more thoroughly (Gordon, 1974).

The appropriate debt/equity ratios, dividend rates, and growth rates vary from industry to industry and also from one size firm to another. All of these factors also impact on the interest rate paid by a firm on its debt. In the United States bond rating services categorize companies by industry (i.e. industrial, utility) and by overall quality within that industry. The long term debt rates charged by the market to firms of varying qualities (Aaa being the highest) and US Treasury Bonds during the 1970s are shown in Fig. 4. For analysis purposes, many firms define their cost of capital as that long term rate that leaves unchanged the market price of the common stock (Gentry, 1977). As a project increases in size in relation to the capital base of the firm, this assumption becomes difficult to maintain. The large swings in interest rates illustrated in Fig. 4 also indicate the problems of assigning a single cost of capital rate to projects with long lives, especially if the firm must borrow at short-term rates to finance long-term projects. Thus, it is evident, a project that might be quite acceptable to one company would be rejected by another who finds its cost of capital is too high in relation to project returns.

It has also been suggested that a firm risk adjust the rate of return by class of investment project as follows (O'Neil, 1979):

Class 1—Replacement of equipment in an ongoing operation. Market is known, technology is proven, so that risk is fairly low. Maybe a discount rate of 10% is acceptable here.

Class 2—Expansion of present mine or plant facilities. Many technical problems have already been solved, but there may be a question in marketing. Can the additional output be sold at pre-expansion prices? The added risk here may indicate that a higher discount is in order, say, 15%.

Class 3—Opening of a new operation, entering a new market, etc. Here the sources of uncertainty are many, justifying, perhaps, 20% as the minimum acceptable rate of return on such projects.

The lowest rate classification should at least be equal to the firm's cost of capital. For moderately risky projects major firms have recently used after-tax rates in the range of 15 to 22% for project evaluation purposes. As mentioned previously, there is no correct rate. The rates are selected based on the firm's strategic goals, past costs, inflation expectations, and management judgment. The selection of an unrealistically high rate for all projects can result in a gradual liquidation of the firm as it will not be able to select sufficient new projects to continue to operate as an ongoing concern.

Expected long term yield must also be carefully evaluated. In 1982 the US experienced a rapid decrease in inflation and only slow moderation in interest rates. The result was that

Fig. 4. United States long-term debt rates.

real interest rates, the difference between the market rate and the inflation rate, were in excess of 6% instead of the 2 to 3% that prevailed in the 1970s. Using current bond rates as a proxy for the discount rate under these conditions would distort the long term valuation of a project if one did not believe this relationship would be maintained over the life of the project.

Accounting for Inflation

During the 1950s and 1960s when prices rose at rates of only 1.5 to 2%, business schools turned their attention to fine tuning of the economy and business planning. With very low rates of inflation and increased access to computer-based analysis techniques, elaborate models could be constructed using indices to adjust prices and costs from one time period to another. Then came the 1970s and early 1980s, which turned both national economic and business planning into a shambles. Basic forecasts for the most volatile years could be in error by more than 20 to 30% per annum. Worse yet, in the mineral industry, conventional wisdom was that prices of a depleting mineral asset should rise to at least equal to or exceed inflation in general to offset the cost of bringing in new production. But, this was not the case for many minerals. A new word was coined, *stagflation*, to indicate that economic growth could stagnate while cost inflation could continue at high rates.

The experience of the Hecla Mining Co. in their attempt to diversify from silver into copper by developing the Lake-

shore Copper Project is but one example of the problems facing the industry. Fig. 5 plots the inflation adjusted cost of copper against the cost estimate for bringing this Arizona mine into operation (O'Neil, 1982). Hecla started work on their underground mining project in 1969 when both the US economy and the price of copper were strong. Ground control and mining problems delayed preproduction development. The scheduled startup date slipped from 1973 to 1975. Cost estimates increased from \$100 million in 1969 to \$185 million in 1975 as capital costs were impacted by the delay and by the first OPEC-induced cost increases. Real copper prices continued to fall and in 1978 Hecla abandoned the project which by then had a total investment of \$200 million. What may have been a sound decision in 1969 almost forced Hecla into bankruptcy in 1978 when their net assets dropped from \$199 million to \$12 million. Only spectacular rises in silver prices in 1979 saved the company.

Inflation is a real problem that has major impacts on the following factors:

1. Interest rates directly reflect the financial community's opinion and current forecast of future rates (which does not necessarily mean it is an accurate forecast). In the broadly based US financial market on any given day interest yield curves can be plotted for securities with varying quality ratings and maturities. Fig. 6 shows both upward sloping curves typical of the pattern as the economy begins to recover from a recession and downward sloping curves that indicate the market perceives long term demand for money will drop.

Fig. 5. Economic parameters during development of the Lakeshore mine.

Fig. 6. Long-term bond yield curves.

Access to long term funds and the timing of financings can be critical to the success of large projects. Fig. 4 illustrates the variability of the US cost of funds during the 1970s.

2. Access to capital in rapidly changing times can be limited. In 1974 the utility industry faced a severe capital shortage as investors became wary of the utility's ability to cope with the changing economy. Likewise, lenders try to lower their risk by shortening repayment terms. This can actually make mining projects more risky as cash flow will be decreased in the usually critical early years.

3. Accounting problems can be significant as reported profits are distorted during inflation. The sale of low cost inventories results in high current profits, but producers must figure new inventory at higher costs, which depresses cash flow. Depreciation charges do not properly reflect the cost of replacing capital equipment. In the US major tax and accounting changes were required to cope with the turmoil caused by the economy of the 1970s. Later in this section taxes and depreciation accounting are discussed.

4. Price and cost forecasting so necessary to proper investment planning becomes difficult as historical trends are greatly distorted and perhaps altered permanently.

There are three basic methods to consider inflation in project cash flow analysis:

Method 1—Constant Dollars, No Inflation: This method values all costs and revenues as of the date of the estimate. It implicitly assumes future costs and revenues will inflate at the same rate. The disadvantages of the method are:

1. Capital costs are not identified at their actual ultimate cost, which makes financial planning difficult.
2. Taxes are underestimated because the value of depreciation is overstated.

Method 2—Inflate All Variables to Startup Date, Hold Constant Thereafter: Cash flows after the startup date are expressed in constant dollars valued as of the startup date. This method is frequently used by financial institutions as it does account for increased capital costs and should be reasonably accurate for the first year of operation when servicing the debt will be the most difficult. However, it still has the following disadvantages:

1. Taxes are still underestimated.
2. Equipment replacement costs are underestimated.

Method 3—Inflate All Variables Over Life of Project: This method provides the most realistic cash flow analysis. One must assume an explicit inflation rate for each year for each variable. Each component of cash flow is inflated over the life of the project. These cash flows are then deflated to the beginning of the project at an average inflation rate to give present values expressed in current dollars as of the start of the evaluation time frame. The principal disadvantages of this method are the number of calculations required and the problem of coming to a consensus as to forecasts for the appropriate values for the component inflation rates. Sensi-

tivity analysis techniques that can be used to assist in studying the impact of changes in assumptions are described later in this section.

Cash Flow Defined

The time value concept previously described relies on the identification and analysis of cash flows that consist of the investment and the subsequent return on and recovery of the investment. During the preproduction stage the investment consists of current expenditures plus capital expenditures (capital being defined for accounting and tax purposes as an investment with an economic life greater than one year). During production, revenues are received from the sale of product, and the cash flow is equal to the revenues less current capital expenditures and current cash expenditures, including taxes. During the post-production phases remaining assets are sold providing a return of investment, and cash is expended for items such as reclamation.

Deriving cash flow from tax and financial accounting statements can be complicated and requires an understanding of accounting. Table 2 shows how the same project would be reported differently for tax, cash flow, and financial book reporting purposes. Net income represents the return on the investment while depreciation and depletion represent a recovery of the investment. Four items requiring special explanation in the determination of cash flow are capital recovery charges, taxes, working capital, interest, and sunk costs.

Capital Recovery Charges and Taxes: Capital expenditures require special handling for financial and tax reporting. Comparison of the statements in Table 2 demonstrates that for cash flow purposes only the actual year's capital expenditures are included in the cash flow. Depreciation, cost and percentage depletion, and amortization are accounting concepts that shift the timing of expenditures for reporting purposes and are more fully described later in this section under taxes. On the tax and financial books these are noncash items in the year they are reported. They do, however, reduce the amount of taxes paid and, thus, in deriving the cash flow they must be added back to the net income reported for tax purposes.

Working Capital: These expenditures would represent the net new investment in product inventories and spare parts and all other net differences between current assets and current liabilities.

Interest and Repayment of Debt: Interest expense and repayment of debt require the outflow of cash and would be included in the calculation. If the interest is associated with the debt initially included as part of the investment, both the repayment of debt and the after-tax interest charge would be considered a repayment of investment. A financially leveraged return results if debt and interest are included (in this case both are excluded so the analysis only represents

the return on the investor's capital).

Sunk Costs: Sunk costs are expenditures that have already been made and may or may not be recoverable. They should be ignored when making investment comparisons. Exploration and nonrecoverable development costs incurred prior to the date of the analysis are examples of the costs that are excluded.

As it may not be clear why these charges should be ignored, consider the following example: Assume \$3 million has been spent to develop ore body A, and ore body B has been found without cost. Ore body B needs \$2 million for exploration after which it can be sold for \$3 million. Ore body A requires \$1 million before it can be sold for \$3 million. If one were to proceed with both projects, the total cash flow for ore body A would be a \$1 million loss, while ore body B would yield \$1 million profit. Yet, ignoring the previous investment which is not recoverable shows a 3-for-1 undiscounted future return for A and only 3-for-2 undiscounted return for B. Thus, continued investment in A is the preferred alternative.

Having now defined time value methodology, discount rates, and cash flow, attention can now be turned to measuring the performance of projects.

MEASUREMENT OF PERFORMANCE

The primary goal of measuring project performance is to establish criteria against which one can distinguish ac-

ceptable and unacceptable projects. The evaluation criteria chosen should (1) be consistent with the firm's primary objective; (2) recognize that bigger benefits are preferable to smaller benefits; (3) recognize that early benefits are preferable to later benefits; (4) be conformable and realistic, and (5) rank the proposals in the order of their desirability (Gentry, 1979).

Over the years numerous project evaluation techniques have been developed to provide guidance in making investment decisions. Both nondiscounted and discounted methods (which are generally considered most reliable because they recognize the time value of money) are currently in use. The most commonly used methods are presented here.

Payback Method

Because of its simplicity, rather than its merit, the payback method historically has been one of the most frequently used measures of performance. Payback is the amount of time required for the project to generate sufficient cash flow to repay the firm's initial investment in the project.

$$\sum_{n=0}^N CF_n = 0$$

This is a nondiscounted evaluation method that does not take into consideration the overall life of the investment nor the timing or size of the cash flows beyond recapture of the

Fig. 7. Payback method.

initial investment. It is most commonly used only as a guideline, particularly in evaluating projects that are extremely risky or where the accuracy of long term data is very uncertain.

If the cash flows are discounted in the following way, the time value of money during the payback period is recognized:

$$\sum_{n=0}^N \frac{CF_n}{(1 + \text{Disc})^n} = 0$$

The resulting discounted payback period is a more accurate measure of these initial cash flows, but it still does not measure the benefits of the project beyond the payback period. At best, it should be used as a constraint or hurdle against which a project is measured and not as a value to be optimized. Fig. 7 shows the discounted payback period must always be longer, but varies with the discount rate.

Net Present Value Method

The net present value (NPV), also known as present worth (PW), of a project is defined as follows:

$$\text{NPV} = \text{PV Benefits} - \text{PV Costs} = \sum_{n=0}^N \frac{CF_n}{(1 + \text{Disc})^n}$$

The present values of both benefits and costs are calculated at the company's required rate of return. Projects with a

NPV greater than zero will at least earn more than their costs at the minimum acceptable return.

It should be noted when this method is used to compare mutually exclusive projects, the project with the highest NPV may depend on the discount rate used to evaluate the project, as illustrated by the following example.

The two projects each require an investment of \$10,000 and the cash flows from the projects are expected to total \$4,380 per year for three years for Project 1 and \$2,433 per year for six years for Project 2. As can be seen in the following table and in Fig. 8, for a discount rate in excess of 7.7% Project 1 yields a greater NPV, while below this rate Project 2 would be preferred.

Discount Rate, %	Present Value—Annual Cash Flows, \$		Project Preferred
	Project 1	Project 2	
0	13,140	14,598	2
3	12,389	13,180	2
6	11,708	11,964	2
9	11,087	10,914	1
12	10,520	10,000	1
15	10,000	9,204	1

Internal Rate of Return (Discounted Cash Flow) Method

Expressed in terms of the NPV method just described, the Internal Rate of Return (IRR) is the discount rate at which the NPV at time zero of all cash flows is equal to zero (the NPV of all benefits is equal to NPV of all costs). For the previous example the IRR's for Projects 1 and 2 are 15% and 12%, respectively. The formula for calculating the IRR is as follows:

$$0 = \sum_{n=0}^N \frac{CF_n}{(1 + \text{IRR})^n}$$

If the project cash flows are uneven, the solution of this relationship involves an iterative trial-and-error process to converge on the exact IRR that sets the NPV equal to 0. The use of the method has been dependent on the availability of computers and advanced electronic calculators. If one

Fig. 8. NPV of two projects vs. discount rate.

must calculate the value manually, then a rough approximation of the IRR that should be used as a starting point in the iterative process is (Whitney, 1979):

$$\frac{0.07}{(\text{Investment Expenditures} / \text{Average Cash Flow})}$$

If the cash flow stream is an even series and the initial investment occurs at time 0, then the calculations can be greatly simplified by using interest tables. The initial investment is divided by the annual cash flow and the resulting factor is compared to the factors given in tables for the present value of an annuity.

The IRR method, also known as the discounted cash flow method (DCF), is today the most widely used by industry to measure the attractiveness of a project. When comparing evaluation criteria between firms, it is important to establish a common definition of the cash flows being discounted. The most common practice is to use total cash flow after tax to compute a return on the total capital invested (ROI) in the project. The result is often referred to as the DCF-ROI.

In some financial evaluations investors may wish to analyze just the return on their equity investment (ROE) net of any debt and debt service requirements. The ROE will then be a financially leveraged return (see the financing section in this chapter). Also, one should be sure that the method of determining the discount rate is consistent (i.e., continuous discounting or discrete). This is often a source of confusion and does vary by firm.

The IRR method has disadvantages, particularly when it is used to compare projects. It does not consider the relative size of the investments nor the annual cash flows. Thus, making comparisons between projects with very different lives or cash flow patterns is difficult. With regard to individual projects, it is also possible to have multiple rates of return that are economically meaningless but mathematically correct. Each time the annual net cash flow changes sign, it will yield an additional rate of return that will satisfy the resulting polynomial IRR equation (see Fig. 9). Fortunately, most projects start with an initial investment period followed by positive cash flows. The problem most typically arises if there are very large reclamation costs after a mine ceases operation, but they can also arise with projects built in overlapping stages during which the additional investments exceed the cash flows from previously constructed portions of the project. In the latter case, it is possible to avoid the problem by doing an incremental IRR on each stage of the project.

Fig. 9. Example of cash flow which will produce two IRR rates.

Profitability Index Method

The Profitability Index (PI), also known as the discounted benefit/cost ratio, is defined as follows:

$$PI = \frac{\text{PV of future benefits}}{\text{PV of future costs}}$$

The present value of benefits and costs are both calculated at the same discount rate. A PI of 1.00 or better indicates the project will at least cover its cost based on the company's required rate of return. The advantage of the PI is that it indicates relative magnitudes and thus enables the comparison of competing projects. As shown in the following example, Project 2 would be preferred even though the NPV's are identical:

	Project 1	Project 2
PV Benefits, \$	1,000,000	300,000
PV Costs, \$	900,000	200,000
Net Present Value (NPV), \$	100,000	100,000
PI	1.11	1.50

Wealth Growth Rate Method

As mentioned previously, the NPV and IRR techniques present problems when comparing projects with different lives because of the implied assumptions regarding reinvestment of cash flows over the remaining life of the project. The Wealth Growth Rate (WGR) method developed by C. W. Berry assumes the positive cash flows are invested at the firm's average reinvestment rate of return (usually defined as the firm's cost of capital) and are compounded at that rate until the end of the longest lived project alternative. (See Fig. 10.) The Wealth Growth Rate is defined as the interest rate that will equate the future value of the capital investment with the future values of the reinvested cash flow from the project (Berry, 1972). Only projects with a WGR greater than the reinvestment rate should be considered.

The technique is best suited for large enterprises where the individual project will not substantially alter the long term reinvestment rate assumptions. Its advantages are that it uses cash flow rather than profit, recognizes the time value of money, and provides for direct comparison of projects.

Growth Rate of Return Method

The growth rate of return (GRR) method is very similar to the wealth growth rate method as it uses the firm's investment rate to discount or compound all project cash flows to a specific point in time. Thus, it is especially useful in evaluating competing projects. Positive cash flows occurring before the selected point in time (t) are compounded at the reinvestment rate while those occurring after are discounted by this rate to time t . The growth rate of return (GRR) is that rate at which the compounded net present value of the investment at t_0 will equal the future value of the positive cash flows at t . (See Fig. 11.) If the project's GRR is greater than the reinvestment rate and also the GRR of competing projects, then it is selected.

This method does not yield multiple solutions nor require the trial-and-error solutions of the IRR method while it provides selection criteria consistent with the NPV and PI methods. The rankings of projects do not change regardless of the time horizon selected. It suffers from the same disadvantages as does the wealth growth rate method.

Competitive Ranking Method

The inability to forecast drastic economic changes one year hence, much less many years into the future as required by the more traditional DCF techniques, has led many ex-

Fig. 10. Wealth growth rate method.

executives to also require projects to be ranked in relation to their competitive production cost position in the industry. New projects are then screened against an upper cost limit. Using this criterion at least assures the firm that if prices fall precipitously for an extended period, higher cost producers will be required to reduce production sooner. Fig. 12 illustrates a copper supply curve developed by a major metals industry consulting firm (O'Neil, 1982). Similar curves for 1982 would show virtually all US producers operating at a loss. It is recommended that this method be used for evaluation of all significant projects.

One should also be concerned with the corollary to the question of investment—what happens if one does not invest? Other industries such as the US auto industry could have benefited greatly if they had not limited their analysis of the immediate profitability of producing a small car to challenge the first imported Japanese cars. By not accepting smaller initial returns, they ultimately lost market share as the Japanese built volume and lowered unit costs.

The competitive nature of most markets also makes it difficult in practice to actually reach DCF projections, especially with regard to cost saving projects. Other firms are also initiating their own programs that could lower overall industry costs and, thus, cause prices to drop due to competitive pressure. The greatest problem associated with competitive ranking is of course finding reliable data on one's competitors. Fortunately for most major mineral commodities, a significant amount of published data exists, and several consulting firms can offer assistance in constructing competitive cost curves.

Accounting Rate of Return Method

The Accounting Rate of Return (ARR) method is used to measure a project's profitability as an annual percentage of total capital investment. Some firms calculate the return

on an annual basis while others calculate it on the basis of an average over a specified period, generally five years.

$$ARR = \frac{\text{Average Book Income}}{\text{Average Book Capital Investment}}$$

OR

$$= \frac{\text{Average Book Income}}{\text{Total Invested Capital}}$$

The method is generally used by firms whose stock is publicly traded. Analysts who follow these stocks do not have access to the results of specific projects, but they compare company performance by measures such as return on equity and return on total assets. Large projects that produce large variations in reported earnings could introduce price fluctuations in the firm's stock. The ARR is an attempt to indicate this impact.

To illustrate the use of the method, assume a project has been capitalized on the books at the end of year one at \$10,000. For book purposes the investment is written off on a straight line basis over ten years and the book profits are as shown in the following:

Year	Book Investment, \$	Book Profits, \$	Annual ARR, %
1	10,000	600	6.00
2	9,000	600	6.67
3	8,000	800	10.00
4	7,000	900	12.86
5	6,000	600	10.00
5 year average	8,000	700	8.75

Another measure is the average return over the total initial investment, which for the previous example is 7% (\$700/\$10,000).

Fig. 11. Growth rate of return method.

Fig. 12. Competitive cost comparison cumulative USA output against USA operating costs, 1980.

The principal disadvantage of the ARR method is it is a nondiscounted evaluation measure. It does not take into account project lives, the time value of money, or benefits such as percentage depletion and accelerated depreciation. The tax and accounting implications of a project are more fully described later in this section.

Profit Contribution Method

The term profit contribution is intended to encompass all of the net earnings impacts of a project as they are forecast to affect the consolidated financial accounting statements. In a full-cycle economic evaluation, a project is carried from a point where it first affects the balance sheet and net earnings through the point where it last affects them. By assuming liquidation of the assets, equipment, and business of the project, all their earning, saving, or benefit-producing power is extinguished and the books cleared. The algebraic summation of all profit contribution elements is equal to the cumulative net cash flow. No discounting is involved over the life of the project. Thus profit contribution is of limited value except that it places a project in perspective as to its possible impact on overall corporate earnings prospects. Its calculation also serves as a check that the balance sheet

treatment of the project and the net cash flow calculations used to prepare NPV or DCF analyses conform.

Maximum Negative Cash Position Method

While not a performance measure as such, maximum negative cash position is an indicator of the magnitude of a project. It does not provide an indication of how long funds are at risk, only the magnitude of the risk. Stated together with profit contribution, it provides some measure of quality. It is useful because it places a project in perspective as to its impact on overall corporate financing requirements and the firm's total financial exposure.

Hoskold Method

In 1877, M.D. Hoskold proposed a mine valuation method that was an attempt to recognize both the high risk of mining and the depleting nature of ore bodies. Today the method is not used by mine financial analysts because it is inconsistent with current accounting, budgeting, and income tax management practices. Unfortunately, in some states of the United States, the method was used to formulate mine property taxation systems, and thus, until the laws are changed, the legacy will remain.

The method assumes two basic premises regarding cash flows:

1. The initial investment is considered to have a *high risk* that will generate a uniform series of profits. The rate of return is known as the speculative rate that would be required to attract investments to similar properties.
2. Because the mine is a depleting asset, the profits will be reinvested at a safe return such that the resulting sinking fund will provide sufficient funds to replace the mine once the original ore body is exhausted.

Fig. 13 graphically demonstrates the Hoskold methodology. As an illustration of the method, assume a mine with a remaining life of ten years is purchased for \$5,000,000. The annual profits are estimated to be \$1,200,000 and can be invested at a safe rate of 10%. The annual amount required for the sinking fund to recover \$5,000,000 in year 10 is \$313,727 per year leaving \$886,273 per year as the speculative profit. The speculative return would be 17.7% (\$886,273/\$5,000,000).

If this project were analyzed on the basis of no sinking fund, i.e., an annuity of \$1,200,000 for 10 years, the returns from the project would equal the \$5,000,000 investment if interest were compounded at 20.2%. The difference between these two rates of return is important. The point to recognize is that the 17.7% speculative return is the result of two separate investments, one yielding 20.2% and the other yielding 10.0%. This implies that the decision to make the investment with the 20.2% return does not require that there also be a decision to make the 10% investment. If this is true, the 10% investment has no relevance in making the decision about the investment having the 20.2% return. Therefore, the 20.2% return, not 17.7%, should be used as the measure of project attractiveness.

The primary disadvantage of the Hoskold method is that companies commonly do not set up sinking funds for recouping investments, just as they do not put depreciation

allowances in a special sinking fund for future equipment replacement. Another disadvantage is that the time value of money is not directly involved in the risk or speculative rate calculation. The risk rate calculation actually takes the form of the accounting rate of return calculation.

Comparison of Financial Measurements

As stated previously, there is no single correct evaluation method for a project. Most firms will use a combination of techniques. Table 3 compares the major methods of evaluation against a number of financial criteria. It should be noted the ARR and Hoskold method are not directly comparable because they rely on profits rather than on cash flow.

Selection of Competing Projects

The advantages and disadvantages of each of the foregoing methods have been briefly described as have the cautions that should be heeded in applying the methods to a particular problem. It should also be noted that the successful use of any of the more sophisticated techniques is very dependent on the assumptions made regarding the data serving as input to the model. The strategic goals of a company regarding growth, markets, and risk capacity must also be carefully weighed when selecting the performance measures.

Two approaches commonly used when comparing competing projects at the preliminary stage are the hurdle and ranking approach. Hurdles are minimum goals that a project must meet in order for it to be continued (e.g., payback in less than five years, or NPV equal to or greater than the firm's reinvestment rate). This approach is particularly well suited for decision making in the exploratory and preliminary development phases where uncertainty regarding the accuracy of many key variables is high. A more rigorous approach might unnecessarily penalize a project in the very early stages.

A ranking approach lists all projects in order of decreasing value as defined by the particular method of measurement

Fig. 13. Hoskold method.

Table 3. Comparison of Financial Measurements

Items for Financial Measurement	Accounting Rate of Return	Payback Period	Discounted Payback Period	NPV	PI	IRR	WGR	Hoskold
Uses profit or cash flow?	Profit	Either	Either	Cash Flow	Cash Flow	Cash Flow	Cash Flow	Profit
Recognizes time value of money?	No	No	Yes	Yes	Yes	Yes	Yes	Yes
Requires reinvestment rate in calculation?	No	No	No	Yes	Yes	No	Yes	Yes
Assumes a sinking fund?	No	No	No	No	No	No	No	Yes
Results in a form of a rate of return?	Yes	No	No	No	No	Yes	Yes	No

(e.g., PI). Again, care should be exercised at the early stages of a project so that slight differences in values do not eliminate a project that may have a lower profitability but a high strategic value to the firm.

SENSITIVITY ANALYSIS AND OPTIMIZATION

All the methods described so far try to interpret, in a consistent manner, a firm's projections regarding future values. The real problem with financial analysis is that no matter how elaborate the procedures, one is still trying to predict the outcome of a vast array of key independent and dependent parameters, many of which, such as overall economic activity, inflation, and cost of funds, are far more complicated than the project itself.

Sensitivity Analysis

A deterministic approach to project variables is the most common method of evaluating future possible outcomes. Each parameter deemed critical, such as ore grade, recoveries, capital costs, operating costs, sales prices, and inflation is varied to determine its effect on the measure of performance. Fig. 14 illustrates the simple comparison of price vs. return on equity. If the percentage change in values of the

parameters with respect to the base or expected case is normalized, a *spider diagram* can be constructed as illustrated by Fig. 15 in order to directly compare several parameters.

The common practice is to select the minimum, most likely, and maximum values expected for each parameter and to calculate the corresponding value of the performance measure. Thus, if one were to consider price, capital costs, and operating costs as the critical parameters, there are 27 specific *what if* outcomes (i.e., $3 \times 3 \times 3$). The financial analyst and management combine their subjective judgments to select the range of values considered most likely to occur and rate the projects accordingly. If all the cases produce performance values in excess of the hurdle values, the decision process is greatly simplified. Unfortunately, many times the studies will produce values above and below the minimum acceptable values. Probabilistic methods described later may be the best method to quantify the likelihood of their outcomes.

Optimization

For any given set of assumptions it is generally possible to optimize the results. Linear programming, an operations research technique that systematically solves simultaneous equations, has been used effectively by integrated mining

Fig. 14. Typical sensitivity graph.

Fig. 15. Typical spider diagram.

companies such as Cerro Corp. to optimize the results of current operations (Anon., 1972). Many variables including metals prices and operating costs such as labor, transportation, raw materials, and capital costs are incorporated in the model together with constraints such as ore grades, quantities, and the availability of purchased concentrates and metals. The Cerro zinc model contains some 370 variables and more than 150 basic equations that solve the problems posed in Fig. 16. *What if* solutions can be found for both current and projected changes in values.

Others have applied the linear programming technique to entire industries in an attempt to determine the complex interrelationship of variables. The nickel industry has been studied (Copithorne, 1973) to determine optimum pricing and marketing strategies. Properly constructed models can be used to determine the competitive ranking of projects and the outcome of future changes in the variables. The principal limitation in using these techniques is the collection of accurate information, especially with respect to one's competitors.

RISK ANALYSIS

In contrast to the deterministic approaches just described, probabilistic methods attempt to relate the expected variance of outcomes in a systematic manner. This permits the analyst and management to more fully express their degree of uncertainty regarding future events. This section does not attempt to cover all the mathematics of probability theory; however, several examples illustrate how the techniques can be utilized.

Discrete Probability Distributions

The assumption of a finite number of independent outcomes implies the ability to assign a unique probability to the occurrence of each variable. As an example, consider a sensitivity study for a new project which consists of capital costs, ore grade, and market prices, each of which could reasonably be expected to be independent. It is assumed a copper mining project will be operated over a ten-year period and management estimates the probabilities of occurrence for each variable as follows:

Capital Costs	Ore Grade	Market Price
\$10MM; P = 0.10	0.45%; P = 0.50	\$0.70/lb; P = 0.05
12MM; P = 0.60		0.90/lb; P = 0.90
15MM; P = 0.30	0.50%; P = 0.50	1.10/lb; P = 0.05

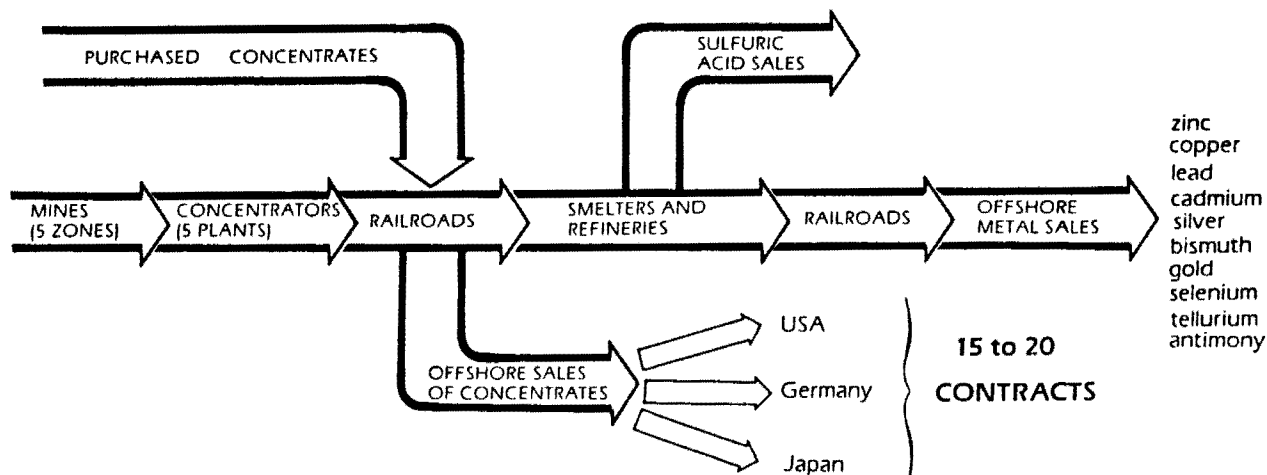

Fig. 16. Cerro De Pasco's worldwide operations.

The probability of a specific combination occurring is simply the multiplication of the probability for each variable (e.g., \$10MM cost, 0.45% grade, and \$0.90/lb price is (0.1) (0.5) (0.9) = (0.045). The probability tree, Fig. 17, shows the possibilities given a mining rate of 500,000 tons per year, direct operating costs of \$700,000 per year, and a tax rate of 50%. There are 18 possible outcomes (3 capital costs \times 2 ore grades \times 3 market prices).

The discounted cash flows range from 5.4% to a high of 26.2% with a mean expected value of 14.1%. Figs. 18 and 19 are histogram plots of the DCF-ROI probability distribution and its cumulative probability. They show an 89% probability the DCF-ROI will be between 9% and 18%. This type of presentation gives management a much clearer idea of the variance of the outcomes.

Conditional Probability

The preceding example was greatly simplified. Frequently, the variables are conditionally dependent on previous events. This is typical of exploration programs as the success of each stage is dependent on the success of the prior stage. A decision tree is shown in Fig. 20 to illustrate the possible outcome of a two-stage exploration program that will result in a property value of \$8,000,000 if successful.

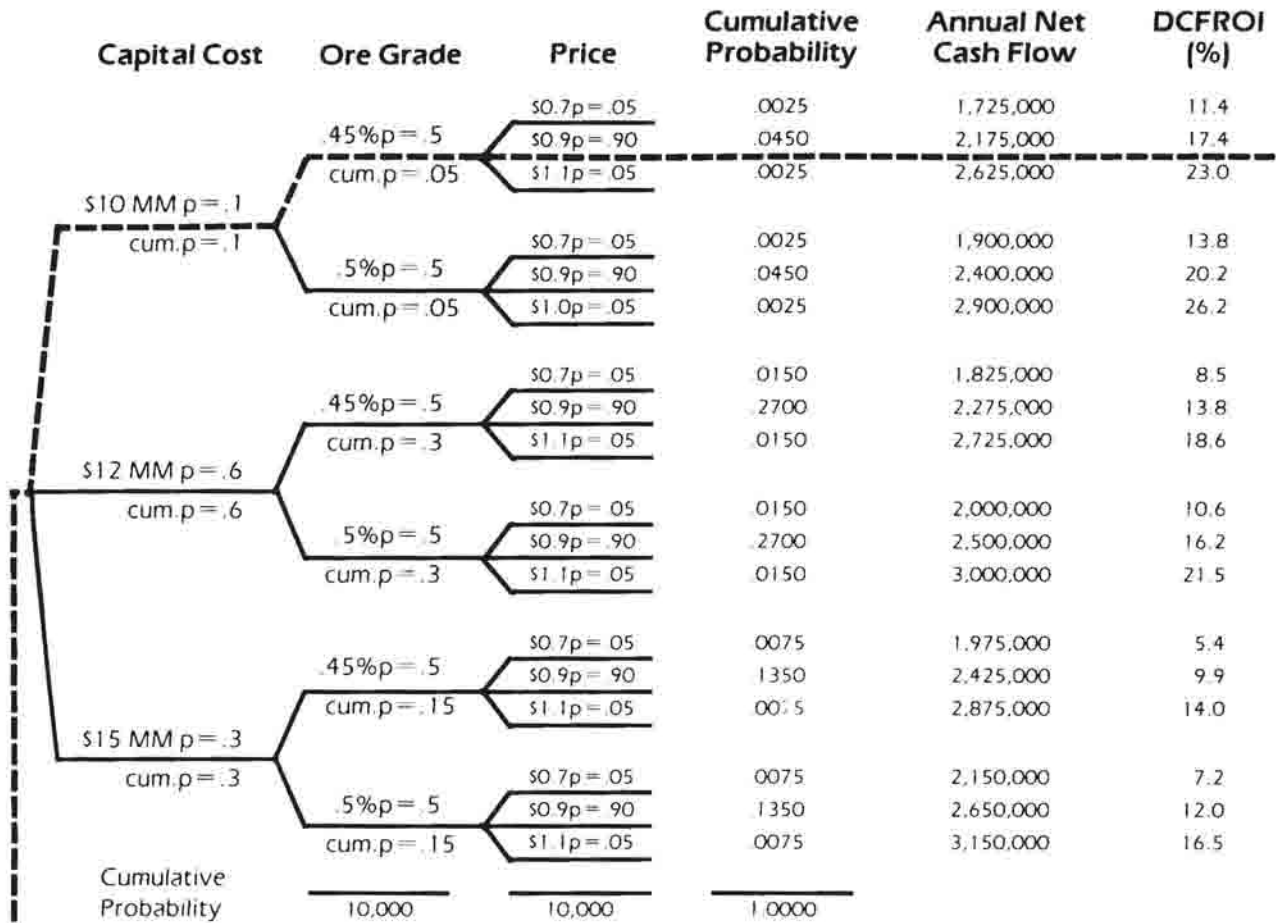

The expected value of this program is less than zero and, thus, would be rejected. The minimum probability of success that would make the company indifferent to the outcome of 2a and 2b is given by the risk capacity equation:

$$P = \frac{1}{\frac{\text{NPV success}}{\text{NPV failure}}} + 1 = \frac{1}{\frac{2,900,000}{5,100,000}} + 1 = 0.6376$$

where P = the risk capacity or minimum acceptable probability of success.

Conditional probabilities will exist between many variables such as ore grade vs. tonnage and ore grade vs. mill recoveries. Thus, care must be exercised in building economic models. A variety of statistical methods exist to determine the degree of dependence or correlation between variables. As a practical matter, a balance must be struck between complexity and the cost of building the model.

Getty Oil Co. is one of the major oil companies that has attempted to quantify the very subjective variables involved

Annual Cash Flow Calculation

Capital Investment	\$10,000,000
Ore Mined (tons/yr)	500,000
Grade	45%
Copper (lbs./yr)	4,500,000
Price	\$.90/lb
Sales	\$4,050,000
less:	
Operating Costs	700,00
Depreciation (over 10 years)	1,000,000
Taxable Income	2,350,000
less:	
Taxes (50%)	1,175,000
Net after Taxes	1,175,000
plus:	
Depreciation	1,000,000
Net Cash Flow	\$2,175,000

Fig. 17. Discrete probability analysis.

Fig. 18. DCFROI probability histogram.

in political risk analysis for foreign investment. The following risk factors are often included in their evaluations:

1. Civil disorder
2. War
3. Sudden expropriation
4. Creeping expropriation
5. Domestic price controls
6. Adverse tax changes
7. Production restrictions
8. Product export restrictions
9. Repatriation limitations
10. Devaluation risk

These factors are related through a series of equations to risk adjust projects for a variety of these occurrences (Bunn and Mustafaoglu, 1978). The company relies on a panel of experts to establish the probability distributions and relationships necessary to solve this extremely complex model.

Continuous Probability Distributions

For discrete probability distributions, the number of possible outcomes is finite. By assuming continuous distributions, one can use statistical sampling methods to generate the probability distribution of the performance measure described previously. This is the basis of Monte Carlo simulation analysis. Common probability distributions that might be considered of each variable are shown in Fig. 21. Referring to the discrete probability example of Fig. 17, the rectangular distribution might be used for ore grade, the normal distribution for price, and the triangular distribution for capital cost.

Using a random number generator, the Monte Carlo simulation method selects a unique value for each variable and sequentially calculates the measure of performance (e.g., DCF-ROI, NPV). The process is repeated a sufficient number of times to produce a stable probability distribution for measure of performance. Complex models may require more than 1,000 simulations. Thus, the method has gained acceptance only as large-scale computers have become available (O'Neil, 1979).

The most important benefit of this analysis is the ability

to compare the risk variance of the possible outcomes for competing projects. Two projects may have the same expected values, but the project with a greater variance may be much less attractive because it is much riskier.

TAXATION

No firm can operate in the US without paying a share of its earnings to the federal and state governments. Tax calculations in the mining industry are complex, and thus careful tax planning is essential to utilize all the available methods of minimizing this cost. Laws are constantly changing, and although this section will outline the pre-1984 basis, some aspects already have changed. The major concepts for calculation of current tax liabilities are expenses, depreciation, amortization, depletion, and investment tax credits (ITCs). Later in the section, deferred taxes, which is a financial concept, will be discussed. Only the current tax liability is relevant for the cash flow calculation, but deferred taxes enter into a firm's reported net income figures. Examples of tax calculations for a project are shown in the Appendix.

The first necessary distinction is between expensed and depreciable project expenditures. Expensed items are those that can be deducted totally from revenue in the year of expenditure. These are generally intangible items, such as drilling costs. Depreciation is a deduction allowed for tax calculations to reflect wear and tear, usage, and obsolescence of equipment and facilities used in a trade or business. Depreciation is over a period of time set by law and can vary from 3 to 15 years, based on the current US tax provisions. Amortization is similar to depreciation, i.e., a periodic writeoff, but applies to intangible assets. Amortization usually applies to relatively small sums in mining projects and will not be discussed further.

Operating costs at an ongoing mine, e.g., labor, energy, and supply costs for mining, milling, administration, and treatment charges, can be expensed for tax purposes. Prior to 1982, exploration and development for a potential new

Fig. 19. DCFROI cumulative probability histogram.

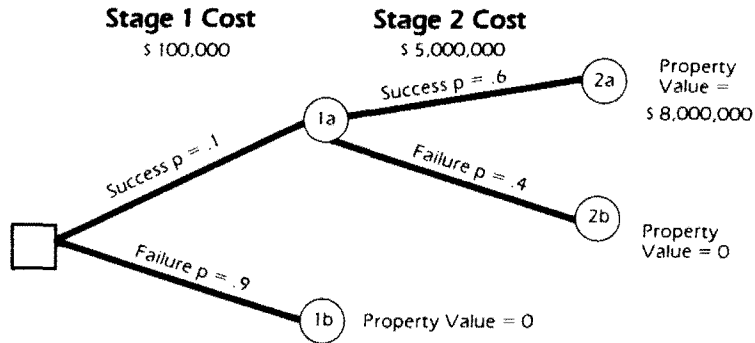

Fig. 20. Decision tree analysis.

The Expected Benefits are Calculated as Follows:

OUTCOME	EXPECTED BENEFIT
1b = (.9) (-100,000)	= -90,000
2b = (.1) (.4) (-100,000 - 5,000,000)	= -204,000
2a = (.1) (.6) (8,000,000 - 5,100,000)	= +174,000
	-120,000

mine had also been fully deductible. Exploration expenditures are defined for tax purposes as expenses incurred in finding and proving the quality of a mineral deposit that had not previously been commercially exploited. The development stage starts once the deposit is defined so that the quality and quantity could justify commercial exploitation. In 1982,

the Tax Equity Fiscal Responsibility Act of 1982 (TEFRA) was enacted. TEFRA allows only 85% of exploration and development expenditures to be deducted in the year spent. The remaining 15%, as well as most equipment and facilities, must be depreciated based on the life of the asset. One other aspect is relevant to exploration expenditures. Any amount

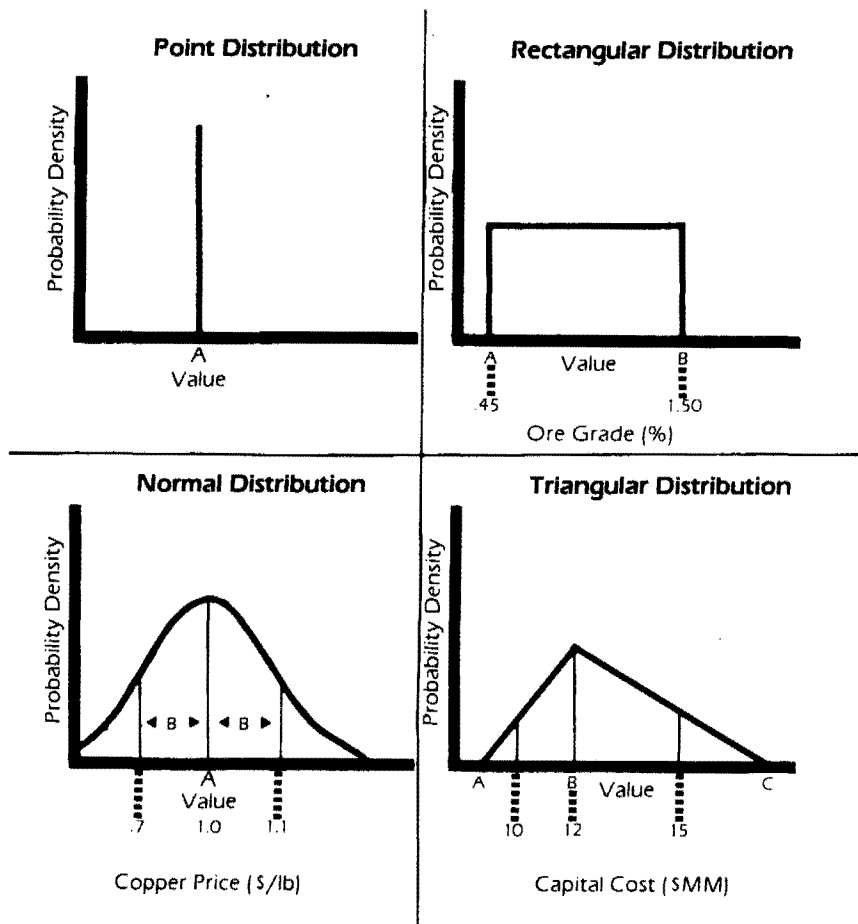

Fig. 21. Four common probability distributions.

that is expensed when incurred is subject to recapture either through depletion or income when the deposit is in production. Both exploration and development expense deductions can also be deferred until the mine is producing. For further explanation of this approach and/or exploration recapture, one of these tax references is valuable (e.g., Coopers and Lybrand, Burke and Bowhay).

TEFRA basically reconfirmed the Accelerated Cost Recovery System (ACRS) method of depreciation established in the major tax legislation, enacted in 1981. In addition to recognizing the inflationary conditions in the economy, ACRS was established to encourage investment, curing faster writeoffs than the previous laws. According to TEFRA provisions, most mining and milling equipment and facilities can be depreciated over five years. Some trucks and other short-lived assets are eligible for three-year depreciation. Buildings generally require a 15-year depreciation period, but if specifically associated with a mining asset such as the mill housing, they qualify for five-year depreciation. Land cannot be depreciated. Depreciation begins once the asset is placed in service, not when the funds are expended. Both new and used equipment can be depreciated on the ACRS system. Salvage value, the value of the item when its usefulness to the firm has ended, is ignored; i.e., the full asset value is depreciated. The depreciation rates are as follows:

Asset Life Year	% / Year			
	3 Year	5 Year	10 Year	15 Year
1	25	15	9	5
2	38	22	14	10
3	37	21	12	9
4		21	10	8
5		21	10	7
6			10	7
7-10			9	6
11-15				

The 1984 Tax Act lengthened depreciation periods for certain assets, so these rates should be used simply to follow the examples.

Tax Credits

ITCs are also available for most mining assets. The credit amount can be subtracted from a firm's tax liability. The credit is 10% for new assets that qualify for five-year depreciation. An asset that qualifies for three-year depreciation is only allowed a 6% credit. Only depreciable assets are eligible for ITCs, i.e., the portion of mine exploration and development expenditures that are expensed do not qualify, whereas the capitalized or depreciable portion does. Land, warehouse buildings, and their structural components, are also not eligible for ITCs unless they are "special purpose," i.e., they house equipment. The other provision relating to ITCs is its effect on depreciation. If ITCs are taken to the extent available, the depreciable base must be reduced by half of the ITC percentage. For example, if a 10% ITC is taken on the mill, then only 95% (100% less 5%) of the mill cost can be depreciated. An ITC is taken the year the asset is placed in service. Advanced ITCs can be claimed on construction progress payments made on property with a construction period of two or more years (provided the property would be eligible for ITCs when placed in service).

ITCs are also available for used equipment, but certain limitations apply. ITCs can be used to offset the first \$25,000 of a firm's tax liability and up to 85% of the liability over that amount. ITCs can be carried back three years or forward fifteen years.

An energy tax credit ranging from 10 to 15% of the investment is also available to firms. This credit can be taken in addition to the regular investment tax credit for qualifying property. The energy credit, however, will not apply to most mining projects. Briefly, it mainly applies to alternative energy property, solar or wind energy property, shale oil equipment, recycling equipment, cogeneration equipment, and qualified hydroelectric generating property (*US Master Tax Guide*, Commerce Clearing House).

Depletion

Depletion is a concept unique to extractive industries. It is based on the concept that mineral resources are exhaustible as well as difficult to replace. Depletion is an additional deduction available for tax calculations. Depletion must be calculated on a mine-by-mine basis, i.e., a firm cannot consolidate its mines. There are two methods to calculate depletion, cost, and percentage (also known as statutory). Depletion must be calculated both ways, and the larger sum claimed. Generally the percentage method is larger. Cost depletion is determined by the basis in the property applicable to the minerals. Thus, if a firm acquires the mineral rights to an undeveloped property for \$2 million, this is the cost depletable basis. Exploration expenditures that are not expensed can be included in this base. This amount can be written off as the minerals are mined on a unit-of-production basis. For example, if the acquired reserves above are mined over ten years in equal amounts, the annual cost depletion is \$200,000. Once the basis has been exhausted or reached zero, no further deductions are allowed. The cost depletable basis is also reduced by any percentage depletion taken on the mine income.

In contrast, percentage depletion does not have a dollar limitation. It is calculated as a percentage of gross income from the mine and varies by type of mineral. Percentage depletion is calculated as the smaller of (1) the product of the set depletion rate for the mineral in question and its gross income from mining (less royalty) and (2) 50% of the pre-tax income calculated without the depletion allowance. No percentage depletion is allowed if income is negative. The depletion calculation for coal varies slightly from this basis, but the idea is similar. However, in this case cost depletion would be greater. Gross income from mining is the revenue derived from the sale of concentrates. In general, royalties, treatment costs, marketing fees, and transportation charges must be deducted. For example, if a company sells refined copper, the percentage depletion is determined on the revenue less smelting, refining, transportation charges, and royalties. The copper depletion rate is 15%. This amount cannot exceed 50% of taxable income before depletion. The cash flow examples in the Appendix further illustrate this concept. If a company is vertically integrated and applies nonmining and mining procedures, it may be impossible to separate the mining and nonmining component costs. A proportionate profits method is available that can be calculated based on profits on return on capital. It should also be noted that the lessor of a property who maintains a royalty interest is entitled to depletion. Taxable income, once determined, is subject to a US tax rate of 46%.

Although a firm is allowed percentage depletion, it is known as a preference item for minimum tax calculations. Firms are liable for a minimum tax on certain preference items. The minimum tax is in addition to the regular tax and is designed to tax income sheltered from current taxation by accelerated deductions. Other tax preference items affecting the mining industry are accelerated depreciation on

real property and amortization of certified pollution control equipment. For further discussion of this, consult a tax reference guide (e.g., *US Master Tax Guide*, Coopers and Lybrand). However, if a firm is taking percentage depletion and taxes are reduced to zero or near-zero, the minimum tax will most likely apply.

State Taxes

State taxes are another cost to a project and can often be significant. Five main types of state taxes exist: (1) ad valorem property tax, (2) severance tax, (3) income tax, (4) sales tax, and (5) excise tax. Further detail of these can be obtained in the reference material or from the appropriate state agency. State taxes now can be deducted as an expense for federal taxes. (This may be changed under revisions to the tax code.) Some states calculate their income tax using the unitary concept. The exact formula varies from state to state, but the tax is calculated based on a percentage of a firm's property, payroll, and sales located within its borders. Each state computes the apportionate formula differently making it possible for a firm operating in several states to be taxed on more than 100% of its income. This tax often results in a higher actual tax than the project itself would generate on a stand-alone basis. Again, consult a tax adviser to determine a basis for this tax.

Capital Gains

Another type of tax is capital gains, which is triggered if an asset is sold for more than its original value. Asset sales are also subject to taxes if the sale is at more than the tax book value. Assume an asset was purchased for \$10,000 and depreciation of \$3,700 has occurred on the tax books, resulting in a tax book basis of \$6,300 (a five-year ACRS asset with two years depreciation). If the asset is sold for \$7,000, then depreciation of \$700 must be recaptured and included as income. This is subject to the 46% tax rate. If the asset was sold for \$11,000, then all the depreciation must be recaptured as income, and capital gains must be paid on \$1,000, the amount over the asset cost. The current capital gains tax rate for firms is 28%. The asset may also be subject to partial ITC recapture depending on the length the firm owned it. An unusual provision exists for coal royalties. These are subject to taxation at the 28% capital gains rate, rather than the 46% ordinary income rate.

Structure and Strategy

The structure of a project can be very important for tax consequences, in addition to legal consequences. Among the areas that are different are at what level tax elections are made, whether tax benefits/losses flow through to other corporate entities, if dividend payout to the corporation is taxable, and if disproportionate allocation of income, expenses, and depreciation is possible. For example, in a partnership, tax elections are made at the partnership level. Likewise, if a corporation is less than 80% owned, then 15% of the dividends are taxable. A tax adviser could define the advantages and disadvantages of each structure.

Tax strategies are available to minimize a firm's liability if carefully considered. One method is to set up a two company structure, a land and a mining company. The land company acquires the property and subleases it (retaining a royalty interest) to the mining company. The mining company develops the mine and pays the royalty to the land company upon production. The land company can take cost or percentage depletion on the royalty income, and the mining company gets percentage depletion. This results in greater combined depletion deductions vs. a one-company structure

where cost depletion is generally lost. Another method to increase income in mining firms is to remove all debt from the mining company, increasing depletion when the 50% of pre-tax income limitation applies. A third method is to remove fast depreciation equipment from the mining company and lease it back using longer lives. These are sophisticated concepts, and before being evaluated and utilized, should be checked thoroughly with a tax adviser as to the precise mechanisms.

Deferred Taxes

The previous discussion on taxes centered around the firm's actual current tax liability. The concept of deferred taxes also exists and is used in financial accounting or to report income figures. Before the discussion of deferred taxes, it is necessary to explain how they arise. The use of ACRS depreciation does not accurately reflect the actual usage of the asset over its life and distorts the tax effects. Thus, for a firm's financial books the asset is usually depreciated on a straight line or units of production basis. These methods allocate the life of the asset more accurately based on its actual usage. The straight line method allocates the cost of the asset equally by years over the actual life of the asset. The units of production method allocates the cost of the asset as a percentage of the production in each year it is used. The table that follows shows the differences in depreciation methods using ACRS, straight line, and the units of production method. The asset is assumed to cost \$1.0 million and has a ten-year life. These examples assume no ITC has been taken; otherwise, the depreciable base would be reduced.

		Annual Production, mm Lbs	Sthousand		
			ACRS	Straight Line	Units of Production
Year	1	5	150	100	50
	2	5	220	100	50
	3-5	10	210	100	100
Year	6-10	12	0	100	120
	Total	100	1,000	1,000	1,000

The financial book reporting system considers this difference in depreciation. It is reflected in the income by showing a deferred tax entry. In early years when tax book depreciation is greater, deferred taxes are positive, whereas in later years, when the reverse is true, deferred taxes are negative. Table 4 shows years 1 and 10 for the mine in the example.

As can be noted, the pre-tax income is \$50,000 higher on the financial book basis in year 1. However, the project is incurring an additional tax cost that must be noted. In years 6 through 10 the asset will no longer enjoy any tax benefits due to tax depreciation. This is reflected in the deferred tax component of \$23,000 which is the difference between the financial book and tax book depreciation adjusted for the tax effects. Likewise, in year 10, deferred taxes are a negative \$46,000. Deferred taxes are a noncash charge, and for cash flow purposes, are an additional source of funds. This simple example ignores depletion on financial books and the effect on deferred taxes due to ITC implications. Only cost depletion, if there is any, is reported on financial books.

FOREIGN PROJECTS

This section is written assuming a US-based firm as the investor. The analysis, however, could apply to a non-US-based firm investing in its country, the United States, or another country. Although the same economic analysis tech-

Table 4

* Treatment of depletion for tax book income may vary by firm.

niques already outlined apply regardless of a project's location, the return may change considerably for several reasons. Even in the United States, taxes vary by state and royalties vary by project. While state taxes and royalties generally have minor impacts on the DCF-ROI or other measures of return, the potential for variation is considerably greater for a foreign project. Taxes, both US and foreign, currency values, currency convertibility, repatriation of cash flow, and expropriation can all have significant effects on a project's return. Perhaps the key point of this discussion is investment outside a firm's country of incorporation involves substantially more complexities and uncertainties increasing the range of potential outcomes and project risk.

Foreign Taxation

Breaking the components that need to be quantified by topic, the most easily quantifiable is foreign taxes. Few generalizations can be made about taxes among countries worldwide since the codes vary dramatically. The first step is to retain an experienced tax adviser to ascertain all the potential tax implications. Depreciation methods can range from straight line to 100% writeoffs. For example, Canada allows certain assets to be depreciated to the extent of a project's income. Foreign tax codes for which items can be expensed also vary. As discussed previously, most stripping and certain other mine development costs can be expensed in the year incurred in the US, but tax treatment of these items varies among countries. In certain countries, additional expenditures may even be expensed. Tax holidays, periods in which no taxes are assessed, are also written in tax codes of certain countries and may often be negotiated where they are not. Mining is often regarded as a strategically desirable industry, i.e., development of natural resources has positive implications for growth, security, power, and independence. One extreme example of a tax holiday is gold production in Australia. Australia currently has no tax on income from gold mines. The same principle of stand-alone vs. integrated may also apply in foreign countries and should be checked. Most

countries allow mining income to be consolidated, i.e., profits from one mining project can offset losses from another. Many countries also allow mining and nonmining projects to be consolidated. (This is dependent on the structure of the firm's operations in that country.) Loss carryforward and carryback provisions should also be ascertained. The allowed time periods are different throughout the world.

The concepts of depletion and investment tax credits (ITCs) should also be investigated. Certain countries have similar concepts; for example, Canada has earned depletion and resource allowance provisions and also ITCs. Another tax that is unique to foreign projects is the dividend withholding tax. Before funds can be repatriated to the US or another country, most countries impose a dividend withholding tax. This tax is not due until the funds are taken out of the country, rather than when earned. The impact of this additional assessment must be considered in the project's profitability.

One important aspect remains to be discussed relating to taxes on foreign projects, namely, the US tax liability associated with the project. If the taxes in the foreign country are lower than the tax would be in the US, the earnings will be subject to US taxes at some time. The US tax liability is calculated according to US tax laws, not foreign laws. Again, this is an area where tax advice is extremely valuable. Depending on the project structure, the tax implications vary widely. Although foreign tax rates are often higher than US and no additional liability will be incurred, certain structures, such as one with a US corporation as the joint venturer in the foreign project, allow percentage depletion when determining the US tax liability. The timing of the US tax liability is also affected by the structure. Taxes can be due as soon as the income is earned or not until it is repatriated. Since numerous structures are available, this area offers high potential for cash flow improvements.

Generally, assets outside the US do not qualify for ACRS depreciation rates per the 1982 TEFRA legislation. Thus, when computing the US liability, slower depreciation rates must be applied. Double declining balance methods are generally allowed.

A further consideration is the concept of creditable vs. deductible foreign taxes. Creditable taxes are those taxes paid to foreign governments that can be used to offset a firm's US tax liability dollar for dollar. Many foreign taxes, such as Canadian federal and provincial income taxes, qualify. The general rule is that the tax must be an income, war profits, excess profits, or dividend withholding tax. However, these definitions are broad, and interpretation from one's adviser and/or the IRS is suggested. Deductible taxes are those that only can be deducted as a project expense for the US tax liability calculations, i.e., they are treated the same as an operating expense. Thus this tax does not offer as significant an advantage as a creditable tax. The Ontario, Canada, mining tax is an example of a deductible tax.

Another consideration for a US-based multinational firm with several foreign projects is the concept of tax pools. If the firm has projects in several countries, worldwide income can be consolidated into tax pools, i.e., a firm can combine earnings from all foreign countries. Further this is not limited to mining projects, but applies to all foreign income. Thus, if in one country, the company is paying foreign taxes greater than its associated US tax liability, and in another country the foreign taxes paid are less than the US tax liability, the one project will generate excess foreign tax credits which can be utilized to offset the US tax liability from the other project. Carryforwards and carrybacks are also allowed on these cred-

its. For reference, the current US regulations allow a carryback of two years and carryforward of five years. The following table shows a simple example of this concept. In reality, the concept is more complex, and the implications of the project on a firm's income should be checked by the tax adviser. This example also assumes the deductions for US and foreign tax calculations are identical, which is seldom the case.

Year 1				
	Country A Tax Rate 30%	Country B Tax Rate 60%	Total Foreign	US Basis Tax Rate 46%
Revenue	100	130	230	230
Costs (including noncash)	70	60	130	130
Pre-tax income	30	70	100	100
taxes	9	42	51	46
After-tax income	21	28	49	

A credit of \$5 (\$51 vs. \$46) is generated to be carried forward or back in this example. Even though the tax rate in Country A is only 30%, the higher tax rate of 60% in Country B prevents this firm from owing any additional liability on Country A's income. Further, a credit is generated which could be partially used in the next year. An example of one way this could occur follows:

Year 2				
	Country A	Country B	Total Foreign	US Basis
Revenue	250	130	380	380
Costs (including noncash)	170	60	230	230
Pre-tax income	80	70	150	150
taxes	24	42	66	69
After-tax income	56	28	84	

The US tax liability is \$69 whereas foreign income taxes paid are only \$66. Thus, the \$3 due to the US can be offset by the previous year's \$5 credit, and a credit of \$2 would still be available.

Other Considerations

Currency values and convertibility of currency are very important parameters. However, it is impossible to predict future currency relationships. Government changes, shifts in demand patterns, oil discoveries, and numerous other factors enter into this component. Noticeable depreciation and appreciation of currencies are very common during mine life periods. This can be particularly important when a firm sells its products in one currency and makes purchases in another. Most readers are familiar with the hyperinflation that has occurred in several South American countries in the 1970s and 1980s. However, exchange rates change widely even among politically stable countries. Consider the Japanese yen vs. the US dollar. The rate has varied from about 170 to 360 yen per dollar from 1970 to the present.

Inflation is a related yet additional aspect. Differential inflation rates among countries can offset changes in currency exchange rates. However, fixed rates preclude this adjustment, and other factors also enter into the relationship. Despite the uncertain nature of foreign currency values and

inflation, some assumptions on both exchange rates and inflation must be made for evaluation purposes. Historical data is helpful, especially for noticing trends. However, this is an extremely uncertain area for evaluation purposes.

Convertibility of foreign currency is another consideration. This relates to repatriation of cash flow to the US and also the currency value at which the funds are repatriated. Often, a country will not allow or only allow a portion of a project's cash flow to be taken out of the country or taken out at a fixed unrealistic rate. If this is the case, the project's cash flow is vastly different from the theoretical cash flow shown by the calculation. Again, this is an important provision in the structuring of the agreement. Contacts with other firms who have dealt with the specific country can be valuable.

Expropriation is another risk in foreign projects, i.e., a firm may be forced out of a country. One way to evaluate this event is to determine the project return assuming some fraction of the project (e.g., 10 years cash flow on a 20-year project) or use the same technique but add a buy-out sum.

To clarify the foreign project discussion, an example was created for the hypothetical project and is shown in the Appendix. No US taxes are ever due since the foreign tax liability always exceeds the US liability. The assumptions for depreciation, tax rates, exchange rates, and other salient factors are shown. This case also assumes the company has no other foreign projects with which to consolidate the project, either in that country or for US tax purposes.

OTHER FINANCIAL/ECONOMICS CONSIDERATIONS

In addition to equity investment decision analyses, a firm often has numerous other financial decisions. Examples include asset sale or disinvestment opportunities, mergers and acquisitions, farm-in/farm-out of properties, shutdowns, rate acceleration projects, post-investment evaluations, and leasing decisions. Discounted cash flow methods are applicable to all of these decisions, but additional analysis is also necessary. This section will highlight the major issues and provide guidance as to important parameters.

Disinvestment/Acquisition

First consider disinvestment, also known as redeployment, or the firm's disposal of a project. What criteria should be used? The first is to evaluate the property on a point-forward basis. The future cash flow of the project should be determined and discounted at some hurdle rate. This rate is often set lower than the investment hurdle rate. If the project has any debt associated with it, that amount should be subtracted from the value. Likewise, working capital at the time of disposal should be considered. If positive, working capital could add value. Major items on the accounts should also be evaluated. For example, some receivables may need to be written off as bad debt. Likewise the value of spare parts may have increased due to inflation. Short-term debt should not be double-counted in the debt components. Tax consequences are also very important. Sale of an asset usually generates taxes, and the amount generated can vary depending on the nature of the sale transaction. Among items to be considered are depreciation recapture, ITC recapture, and capital gains taxes. Once the after-tax value of the asset is determined, a firm has an idea of an acceptable price. However, strategic considerations are often important and should not be overlooked. If this project has nonquantifiable synergistic effects with other projects, marketing programs, or

another area of the firm's business, these factors should be weighed in the decision.

Mergers or acquisitions are similar to disinvestment except the firm is the buyer rather than the seller. Again, a discounted cash flow method is appropriate to determine the value of the asset. Other performance measures, such as competitive position and market share, can be ascertained. Factors such as strategic goals and cash availability are also important. A firm has some flexibility here on how to acquire an asset. Different methods are available such as stock for stock, stock for assets, etc., and can result in different depreciable bases for tax books (a real dollar effect). Debt and working capital should again be quantified from the purchaser's side. Potential liabilities, e.g., pensions, lawsuits, environmental problems, should also be assessed.

Farm-in/farm-out analysis is a form of acquisition/disinvestment. Payments for purchase or sale occur over time in the form of capital investments, options, royalties, lump sum amounts, percentages of income or cash flow, or other varied methods. Here again, the cash flow streams for one's firm have to be separated from the total project cash flow. The present value at desired discount rates and/or DCF-ROI can then be calculated. If these are revenue or income dependent, price sensitivity analysis is highly desirable.

Shutdown

Shutdown decisions are often only near-term decisions but may be long term if a mine's reserves are almost depleted or the mine occupies a very high cost position in a glutted market. Shutdown, care and maintenance, and startup costs should be determined and compared to the operating cash flow for the period of time in question. Several sets of shutdown time frames can be evaluated to consider shorter and longer economic recovery periods. All costs that will be ongoing, such as property taxes, fixed power contract base amounts, or other fixed costs should be included in the shutdown cash flow. If a permanent shutdown is being considered, tax and salvage effects can be very important. Assets can be sold or written off, but reclamation may also be required. A determination of these amounts and their tax effects is needed.

Rate Acceleration

Rate acceleration analysis involves whether to increase the size or move forward the timing of a project. The opportunity involves more cash in early years at the expense of foregoing cash in later years. Thus, two cash flows can be determined and often two DCF-ROIs result. One method of handling this is to compare the present value for acceleration vs. nonacceleration. This should meet the minimum corporate present value hurdle rate. More sophisticated analyses use the double DCF-ROI concept. The upper return should be compared with the firm's DCF-ROI hurdle rate (i.e., the project can compete with other company investment opportunities). The lower return is the rate the firm would be willing to pay an outside party to fund that project. As this is a very brief discussion of rate acceleration, further reading on this subject is recommended if utilization of this analysis is desired.

Post-Investment

Post-investment analysis, the evaluation of an ongoing project vs. its expected performance at the time of acceptance, is often overlooked despite its significant value as a tool for future decision making. This involves a search through a firm's books to determine the actual performance. The future for the project should also be assessed in the current envi-

ronment. Often this analysis provides management with disinvestment candidates, shows areas in which strategic mistakes were made, or points out a changing environment for future project analysis and direction for the firm.

Leasing Decisions

Another area of economic decision-making a firm may face is the lease vs. buy or lease vs. do-nothing analysis. If an asset in an investment proposal (or even the total proposal) may be either purchased or leased, the investment evaluation must first be performed to see if the asset should be acquired at all. This decision is based on the firm's hurdle rate and other competing investment opportunities. If this analysis indicates that the asset should be acquired, then the next step is to perform the lease vs. buy evaluation to determine how the asset should be acquired, i.e., lease or purchase. The after-tax cash flow associated with the lease should be determined and subtracted from the purchase cash flow and the discount rate determined. (For simplicity, costs identical to each case need not be included since the net effect is zero.) This will equate to the implicit interest rate associated with the lease. The relevant criterion to judge this return is based on the after-tax cost of corporate long-term debt. (Leases can be separated into categories, e.g., financing and operating, with separate debt rates set for each.) Table 5 presents an example of this analysis. This example only includes the costs/savings that are different for each case.

Table 5

	Year	Buy
Purchase	0	(1000)
Depreciation savings/ITC	1	171
Depreciation savings	2	104
Depreciation savings	3	100
Depreciation savings	4	100
Depreciation savings	5	100
Total		(425)
	Year	Lease
Lease cost	0	—
Lease cost	1	(130)
Lease cost	2	(130)
Lease cost	3	(130)
Lease cost	4	(130)
Lease cost	5	(130)
Total		(650)
Buy less lease costs	Year	
	0	(1000)
	1	301
	2	234
	3	230
	4	230
	5	230
Total		225

Assumptions:

1. 5-year asset life/5-year lease
2. ACRS depreciation (95%)
3. 10% ITC on purchased asset in year 1
4. \$1000 purchase price
5. Annual lease cost of \$260 (before tax)
6. 50% income tax rate
7. All other revenues and costs same for both lease and purchase

Result: DCF-ROI = 7% (Mid-year continuous discounting)

The example yields a DCF-ROI of 7%. If the after-tax cost of debt for the firm is greater than this amount, the asset should be leased. The project life used in both the lease and purchase cases must be equivalent for the analysis to be correct. If lease payments extend beyond the project life, they should be included or replaced by an appropriate buy-out penalty. Similarly, if salvage or depreciation tax credits extend beyond the project life, they should also be included. If sensitivities are investigated, they should be performed on both the lease and buy evaluation on equivalent bases.

This calculation does not consider strategic factors. If a firm is capital short, leasing may be the only option. Leasing may also be desirable if the asset may soon become obsolete or if upgrading is possible.

The lease vs. do-nothing evaluation is more intangible. Two steps are required. First, a hypothetical purchase option that is equivalent to the lease option at the allowable cost of leasing should be developed. This can be accomplished using the lease vs. buy evaluation procedure. Second, an equity investment evaluation should be performed using the hypothetical purchase option. If the hypothetical purchase option is acceptable, then by definition the lease is acceptable since the lease is equivalent to the purchase.

CONCLUSIONS

The foregoing discussion was intended to acquaint readers with economic and financial analysis. An appendix is included with examples that should aid in performing the cash flow or other investment techniques discussed. Again, we would like to emphasize the quality of the input data and the importance of sensitivity analysis. A DCF-ROI based on scoping data may be highly inaccurate. Price assumptions are often the most important. Low metals prices have caused the downfall of many projects and greatly affected the financial position of many firms.

APPENDIX ASSUMPTIONS CONSTANT DOLLAR CASE

Production

10 year life

	Year 4	Years 5-13
Copper (million lb)	75	100
Gold (thousand oz.)	30	40

First year production figures recognize startup inefficiencies—production at 75% of capacity.

Prices

Copper: \$1.00 per pound
Gold: \$500 per ounce

Operating Costs

	\$ million/(\$/lb)			
	Year 4		Years 5-13	
Mining	20.0	(.27)	20.0	(.20)
Milling	15.0	(.20)	15.0	(.15)
Treatment	22.5	(.30)	30.0	(.30)
Administration	5.0	(.06)	5.0	(.05)
	62.5	(.83)	70.0	(.70)

Mining, milling, and administration costs were assumed to be the same for the startup year (year 4) to reflect inefficiencies. Treatment charges based on actual pounds treated.

Capital Costs

	\$ million			
	Year 1	Year 2	Year 3	Total
Stripping and other expensed items	5	20	5	30
Mining equipment	10	10	10	30
Mill, crusher, other facilities	20	30	40	90
Total	35	60	55	150

All prior exploration and development costs are assumed to be sunk costs and thus ignored. Sustaining investment of \$2 million in years 5 and 6, and \$4 million in years 6, 7, and 8.

Tax / Depreciation

Development: 85% expensed in year of expenditure
15% capitalized — 5 year ACRS depreciation on 95% upon production.

Mine, Mill, Facilities: 5 year ACRS depreciation on 95% of expenditures. Depreciation begins when assets are placed in service, i.e., mining equipment depreciation starts in year 1. This is a simplifying assumption since some assets enjoy faster depreciation and others (e.g., buildings) have slower rates. 95% rate is used since 10% ITC is taken.

Tax Rate: 50% tax rate upon startup
46% tax rate in development years
50% rate (years 1-3) assumes both federal and state taxes. Lower tax rate assumed in development years since many state taxes are based on revenues and thus credits are not available in development years.

Investment Tax Credit: 10% in year of expenditure
Assets not placed in service immediately are assumed to have two year or longer construction periods and thus qualify.

Depletion: 15% of revenue less treatment charge up to a maximum of 50% of pretax income.

The tax assumptions used in this example assume the tax losses can be consolidated with the firm's other income for US tax purposes, i.e., the firm is profitable (this is not a stand-alone case).

Working Capital

Assumed to be two months of revenues. This is a simplifying assumption and reflects spare parts inventory plus other effects, such as timing differences in payables and

receivables. Note working capital increases from year 4 to 5 as revenues increase. All is recovered at end of project.

Royalties

None.

Inflation

None since this is a constant dollar example.

Economic Results

DCF-ROI, %: 17.1 (mid-year continuous discounting)

See Table A.2.

Present value, \$ million

@ 13%: 26.3

@ 15%: 12.3

Payback period: year 7

Maximum cash out,
\$ million: 121.0 in year 3

See Table A.1.

ASSUMPTIONS FINANCIAL BOOKS — ESCALATED DOLLAR CASE

Production, Prices, Operating Costs, Capital Costs, Working Capital, Royalties, Inflation, Economic Results

Equivalent to escalated dollar case.

Tax/Depreciation

Development, mine,
mill, facilities: 10 year straight line depreciation on 100% of asset value.

Sustaining investment: 5 year straight line depreciation on 100% of asset value.

Current taxes: Same as tax books. 46% rate prior to startup. 50% rate upon startup. Some investment tax credit and depletion assumptions.

Deferred taxes: Calculated as the difference between tax book and financial book depreciation times the tax rate in that year. The only years that deviate are years 1 and 13. Since only 95% of assets are depreciated on the tax books, the remaining 5% is added to the first year tax book depreciation for deferred tax calculations. Likewise, the difference between the 46% and 50% tax rates generates a difference which is balanced out at the end of the project.

Return on capital: Ratio of financial book income to average capital employed. Average capital employed is the average of the beginning of year capital employed and the end of year capital employed. Capital employed at the beginning of the project is zero (nothing has

been invested to date). End of year capital employed is net income less net cash flow. For example, year 1 has a beginning of year capital employed of zero and an end of year capital employed of $3.3 - (-31.0) = 34.3$ for an average capital employed of \$17.5 million. Also capital employed at the end of the project is also zero.

ASSUMPTIONS FOREIGN PROJECT ESCALATED DOLLAR CASE

Production/Royalties

Same as constant dollar example.

Prices, Operating Costs, Capital Costs

Base level same as constant dollar example.

Inflation

Same as escalated dollar case. This assumes inflation is the same in the foreign country as in the United States. Six percent per year for all capital costs, operating costs, and prices.

Working Capital

Same as escalated dollar case. Assumed to be two months of revenues.

Exchange Rate

Figures shown in US dollars. Exchange rate held constant throughout, i.e., dollar and foreign currency value relationship is the same throughout the project.

Tax/Depreciation

Development, mine,
mill, facilities: Eight year doubling declining balance depreciation converting to eight year straight line depreciation when latter exceeds the former. Depreciation begins upon production.

Sustaining investment: Five year doubling declining balance depreciation converting to five year straight line depreciation when latter exceeds the former.

Foreign taxes: 60% upon startup. Tax losses carried forward and utilized against profits. No investment tax credits. 15% withholding tax on dividends. Assumes dividends repatriated as earned.

Depletion: None.

US Taxes: None due since foreign liability exceeds US liability.

The tax assumptions used in this example assume the firm either has no operations in that country to utilize tax losses and/or that tax losses cannot be consolidated, i.e., this is a stand-alone example.

Economic Results

DCF-ROI, %:	10.8 (mid-year continuous discounting)
Present value, \$ million	
@ 13%: (17.3)	
@ 15%: (30.0)	
Payback period: year 9	
Maximum cash out, \$ million:	170.0

Comments

The higher tax rates (both foreign and dividend withholding), no pre-production tax benefits, and lack of ITC and depletion cause the return to drop noticeably from equivalent US project (10.8% vs. 21.8%).

See Table A.3.

ASSUMPTIONS ESCALATED DOLLAR CASE

Production, Tax / Depreciation, Royalties

Same as constant dollar example.

Prices, Operating Costs, Capital Costs

Base level same as constant dollar example.

Working Capital

Assumed to be two months of revenue as in constant dollar example. Working capital increases every year due to inflation of prices.

Inflation

Six percent per year for all capital costs, operating costs, and prices. As an example, year 1 copper prices are \$1.06 per pound, gold costs are \$540 per ounce, and capital costs are \$37.1 million. The equivalent figures in the constant dollar example were \$1.00 per pound, \$500 per ounce, and \$35 million.

Economic Results

DCF-ROI, %:	21.8 (mid-year continuous discounting)
Present value, \$ million	
@ 13%: 76.8	
@ 15%: 53.1	
Payback period: year 7	

Maximum cash out, \$ million:	137.4 in year 3
-------------------------------	-----------------

Comments

The inflation causes the DCF-ROI to rise since all parameters are increasing at the same rate. This may not hold true if different factors escalate at different rates. Note also that the total cash flow is higher as is the maximum cash out.

See Table A.4.

4.4 Project Financing

GENERAL CONCEPTS

EDWARD VICKERS

Financing has always been an important consideration in resource development, but today it has reached the point where it may well be the controlling element in bringing an ore body into production. The proper application of financing to a project may be the difference between success or failure of the venture. Financing and technical considerations are not independent, but are inexorably linked. The engineer today must be aware of financing implications every step of the way, from the beginning to the completion of a feasibility study. This is not to suggest that the engineer assume the role of the corporate treasurer, but rather that the two arms of management must work in close concert to achieve the desired result.

The role of the mining company is shifting from its classic position of an organizer and provider of funds to that of a sponsor, providing the upfront risk money and managers of the project. In this environment, new partnerships are forged. These partnerships take on many forms, but certainly the lender is one of the most important partners. Other partnerships are also forged by the joining together of more than one mining company, offering host country participation, and, due to the heavy reliance on sales contracts, even involving the purchaser of the product. As a partnership takes form, a new project emerges as a separate entity, a new mining company in other words, relying heavily on its intrinsic worth to attract the capital needed to bring it into production.

Financing costs of a new venture are often equal to, or exceed, all of the other operating costs put together. These costs are real and demanding on the cash flow of the mine. It is no longer satisfactory for the engineer to address himself only to the technical issues that give rise to an optimum mine design. He must focus equally on the implications of this design on the financing of the ore body. If the cost of financing is not considered, the engineer may feel free to employ his skills constrained only by the characteristics of the ore body in the development of an optimal exploitation system. These design characteristics include scale of operation, annual output of metal, timing of both the construction and production. In the real world, however, each of these factors significantly affects the financing requirements, and the credit strength that the deposit can convey to the suppliers of capital. The highest possible profit from an ore body may well become subservient to the financing constraints. A mining venture of any particular size is only financially attractive if it reflects a desired profit and at the same time is able to service its debt obligations.

Let's begin with fundamentals. What is a banker going to look for? The process of credit evaluation begins with a detailed analysis of the project. Lenders look specifically to the realism of stated assumptions. This often requires independent validation of the major aspects of the venture. In particular the lenders will be concerned with the level of capital cost, contingency provisions, provisions for overruns, ore reserves, operating cost estimates, scope of the project, availability of labor and materials, lead time for delivering critical items of equipment, and possible infrastructure requirements. A great deal of time is spent by the lenders in

evaluating price assumptions. The purpose of this analysis is to quantify the risk associated with the project's development. Lenders want to be assured firstly, that sufficient funds are available for the cost of the project, including any potential overruns, and secondly, that future cash flow generation will be sufficient to meet the assumed debt obligations.

Mine finance, whether it be general corporate borrowing, or project financing, is ultimately characterized as cash flow lending. Security instruments for the lender will be taken on the fixed assets of the property, including a lien on the reserves. This may be viewed as having great value from the mining company's perspective, but the lenders will place little reliance on it in terms of its liquidated value. Their focus will be on the expected cash flow from the property, and the reliability of such cash flow.

Against this backdrop, let us focus for a moment on what is often described as project financing. Many definitions exist, but primarily, it is the financing of a particular mine, in which the lender is looking principally at the cash flow and earnings from the mine as the source of funds from which the loan will be repaid, and secondarily, at the assets created by such financing as collateral for the loan. This differs from normal corporate borrowing, in that the funds are specifically linked to a project with the loan secured by the venture itself but not necessarily guaranteed by the mining company which is sponsoring the project.

The first step in the development of a financing plan for a particular project is the realistic determination of the amount of borrowing such a project can support. Traditionally debt equity ratios of 20 to 25% might well define the level of borrowing. To the degree that the lender is asked to take a higher risk, this ratio is more likely to be in the one third-two thirds range. The degree of leverage the project can withstand depends basically on two factors. First is the ability of the project to meet the scheduled debt repayment in a satisfactory manner. The second is to maintain a level of commitment on the part of the borrower that the lenders on a subjective basis feel is necessary to assure a serious commitment. The normal project loan will generally permit an initial grace period of from two to four years, during which time interest only will be payable on the debt. The total length of a loan will include this grace period. There is no exact rule as to the maturity of any given financing. It is a function of capital markets at the time, the risk inherent in the project, and a number of other considerations. The commercial banks will normally be providing funds for 8 to 12 years, including the grace period. Institutional lenders very often may be persuaded to go up to 15 years. These lenders, however, are much more security conscious and it thus becomes a tradeoff from the sponsor's point of view between maturity and credit support. The credit repayment terms will normally be a level amortization of the principal with a declining interest component as the debt is reduced.

The building block of project financing is basically the process of the allocation of credit or risk in a project. The most fundamental element of security is, of course, the ore body itself. Beyond this basic concept, a number of credit instruments and credit support considerations can be applied to give rise to a financeable project. Completion guarantees, working capital and deficiency agreements, requirements with respect to the minimal level of production, sales con-

tracts, insurance coverage, all form a package that creates the financial strength necessary to meet the lending criteria.

In assessing the viability of the project, the lenders must first be convinced that the project will indeed be completed and performed according to the general specifications set forth in the feasibility study. This kind of assurance is normally provided, by the sponsor of the project, in the form of a completion and performance agreement. It is at this juncture that many projects without senior sponsors have their most severe problems. A junior mining company may well have a very attractive project with outstanding capabilities of producing a highly reliable cash flow, but not have sufficient financial wherewithal to assure the lenders that the project will be completed at the anticipated cost. Realism on this issue is fundamental if the project is to be viable.

Without creditworthy sponsors, some form of an association with an institution capable of supporting these undertakings will be essential. It is only after performance and completion has been achieved that the lenders will be relying on the project cash flow for repayment. Until that time, regardless of the problem, the lenders want others to shoulder those risks.

With performance and completion having been achieved, the lenders are now relying on the cash flow of the venture to provide the debt service requirements. This, however, will not be done on the basis of spot marketing of the product. With the growth of project financing, the role of sales contracts has increased substantially. A lender may be willing to take certain commercial risks but the ability to sell the product is not one of these. Long-term contracts are unquestionably one of the most important aspects of project lending. These contracts must have a number of special characteristics to be satisfactory to the lenders. By and large, they have to extend beyond the term of the lending, provide either a floor price or margins sufficient to insure debt service, and, of course, levels of production necessary to achieve such ends.

This arrangement takes the miner away from the more traditional spot sales and forces him to live with a consumer over a long time frame. As such, the character of long-term contracts has undergone significant changes. They must incorporate escalation provisions to insure that margins can be maintained. These generally are not a single price escalator but cover a whole range of cost factors with an attempt to keep them on a current cost basis. However carefully this is done, contemplating changes in the economic environment of a long time period is a difficult task. For final protection, many contracts have some form of a gross inequities provision. This has the effect at times of opening up a contract to the detriment of either the buyer or the seller. Similar provisions with respect to regulatory changes can result in an interruption in the flow of the product. All such changes or cancellation provisions become very worrisome to the lenders. This results in something of a tug-of-war over the various objectives sought in long-term contracts. The lenders will immediately seek out anything that can cancel the contract. To insure against cancellation, however, can often have negative ramifications on the economic attractiveness of a venture.

In the optimal design of a financing plan, a significant but relatively new force has come into play. This is the heavy emphasis on tax considerations. Perhaps more than in any other industry, the federal government is truly a partner in any mine development. Tax considerations can significantly affect the economics of a project. Tax implications are found in preproduction expense, depletion, depreciation, investment

tax credits, and in the case of coal, royalty income. These considerations affect financing in that reducing taxes provides a greater cash flow for debt service. To take maximum advantage of tax benefits can have the net effect of significantly reducing financing costs.

A traditional form of financing that relied principally on tax timing considerations is lease financing. Leasing had its birth more in the transportation and computer field, but it is finding more and more markets in the mining structure, particularly coal. Many coal developers are simply not in a sufficiently high tax-paying position to make maximum use of investment tax credits and accelerated depreciation. Ideally suited for lease financing are large ticket items in open pit operations. Underground equipment can likewise often be leased effectively but its short life takes away some of the advantages. In the same way that lease financing is attractive because of unused investment tax credits and depreciation, other tax considerations can be employed in mine financing. It is beneficial if preproduction cost and depletion shields are in the hands of taxpaying entities, but to achieve this often involves transfer of mineral ownership. Such transferences certainly introduce a significant complication to financing, but the benefits in reducing financing costs can justify the time and effort involved. Conceptually, one can go as far as to consider structures similar to a sale and lease back to a total mine. Optimal use of tax considerations in mine financing is a somewhat specialized tax field with only a few players at this point in time. Tax-oriented financing structures will no doubt become increasingly important in mine developments.

A feasibility study is a complex undertaking requiring careful analysis of many variables to insure the most economic development of an ore body. It may take six to twelve months to complete and cost anywhere up to a million dollars. Financing considerations are often left to be accomplished, unfortunately, in a few short weeks, and often times by those unfamiliar with the implications of technical decisions already cast in stone. In light of its tremendous significance on the variability of the project, financing considerations should be highlighted and carefully considered throughout all aspects of the feasibility study. In the final analysis, it is the proper marriage of both technical and financial considerations that gives rise to a viable project.

PROJECT PLANNING AND THE FINANCING DECISION

TOMEK ULATOWSKI

Introduction

The financing of any major capital-intensive project, is normally predicated on three factors: first, on the economic viability of such an undertaking; second, on credit terms and its structure; and third, on the general availability of credit. The examples used in this article demonstrate the relevance of concurrently considering these factors in designing an appropriate financing structure for a project.

To illustrate how sensitive new investments are to changes in financial variables, an interactive computer model has been built using hypothetical operating and capital cost values.*

* Content is based in part on "Importance of Financing in Project Planning," by T. Ulatowski, *Mining Engineering*, June 1978, and "Mine Financing: When Is the Best Time to Borrow?" by T. Ulatowski, E. Frohling, F.M. Lewis, *Engineering and Mining Journal*, May 1977.

In all simulations, operating costs were projected in constant terms. The significance of a particular financial variable change was equated in terms of resulting breakeven price per ton of product. It was assumed that the simulated project was self-standing, and it had to demonstrate economic viability on its own.

Significance of the Debt Coverage Ratio

One of the first steps typically taken by a lender in analyzing the financial viability of projects is to test the projected cash flow stream before debt service to the anticipated debt charges (interest and scheduled debt principal repayments). This ratio, calculated on an annual basis, is referred to as cash flow debt coverage ratio (DCR).

The lender must be satisfied that the projected revenue stream is not too optimistic and that the operating and capital costs are conservative. Since the intent of this article is to illustrate the importance of financial parameters on a project, sensitivities of nonfinancial variables are left out. Without doubt, however, they are equally important to any potential lender.

In most cases, lenders require that the debt coverage ratio in any given year be considerably above 1.0. The actual expected ratio will depend on a variety of factors such as, creditworthiness of the sponsors, strength and type of completion undertakings, product purchase/sale agreements, degree of leverage, country credit standing, level of confidence in the projections, sociopolitical considerations and others.

The impact of varying this criterion on the required price per ton of product is illustrated in Fig. 1. If the lender were satisfied with a DCR of 1.20 in any given year he would lend on the basis of a projected price of \$73.5/ton in the first year of operations. On the other hand, should the lender

require the DCR to be 1.80, the price would have to be \$115.3/ton. In most projects, lenders expect to have a projected debt coverage fall within the range of 1.20 to 1.60. Since the product price is independent and cannot differ significantly from the market, such increases in the required DCR could make the project unrealistic as the resulting breakeven price would vary too much from the lender's conservative forecast. Therefore, it is essential for project sponsors to develop high quality information that decreases risk and may lower required DCR. In summary, debt coverage ratio may be viewed as a quantitative instrument employed by creditors in measuring a project risk.

Impact of Leveraging on Project Economics

One way to improve the creditworthiness of a project is to lower the leverage, i.e., the ratio of total debt to equity. The results of the simulations in Fig. 1 were based on a debt/equity structure of 75 to 25. Fig. 2 demonstrates the dramatic improvement in financeability of a venture achieved by reducing the leverage ratio first to 50/50 and then to 25/75.

The minimum breakeven price in the latter case could be as low as \$48.9/ton, assuming a DCR of 1.3, whereas it would have to be increased to \$89.2/ton if the project were leveraged to 75/25.

There is a direct correlation between lender's risk, debt coverage, and leverage. It must be recognized that in extending credit, a typical lending institution is not in a position to accept a great deal of risk. Therefore, to attract financing, sponsors must structure projects in a manner that minimizes the lender's risk exposure. One way to accomplish this is to increase the effective amount of equity in the project through the injection of common equity and also, if necessary, of subordinated debt.

Fig. 1. Impact of debt coverage ratio (DCR) on price per ton.

Fig. 2. Impact of leveraging on price per ton.

Debt Structure and Project Economics

Other things equal, projects in countries with healthy economies and access to extensive capital markets will attract the most desirable financing terms. For instance, a prime borrower in the United States today could place bonds with a maturity of up to 30 years. A similar borrower in a developing country would most likely have to be satisfied with commercial loans carrying overall tenor of no longer than 8 to 12 years from the time of obtaining commitment to the date of last installment repayment.

The implications of this for project sponsors are illustrated in Fig. 3. The longer the overall loan tenor and repayment period, the more attractive are the project economics and the more financeable is the venture. For example, by holding debt/equity constant at 75/25 and assuming the required DCR of 1.3, and then varying the period of debt repayment from 5 to 15 years, the minimum price required by lenders drops from \$89.2/ton to \$59.9/ton.

It is imperative, therefore, that the project sponsors evaluate all possible financing sources with great care, keeping in mind that the tenor of credit is one of the most crucial variables in establishing the viability of a new project.

Unanticipated Capital Cost Increases

One of the greatest areas of concern to a potential lender in financing a new project is the risk of unanticipated capital cost increases. The risk the lender faces is basically twofold: noncompletion, caused by insufficient funding or delay, and deteriorated economics resulting from unanticipated capital cost overruns. The first concern is normally dealt with via requirements that sponsors issue irrevocable and unconditional completion guarantees releasable only upon satisfaction of predetermined completion criteria. The second concern results from the fact that higher capital costs, even

if funded by the guarantors, usually produce lower cash flows. From the standpoint of a lender if the unanticipated cost overruns are funded with senior loans, the actual DCR would deteriorate in relation to the projections and lenders' risk would, therefore, increase.

In Fig. 4, the basic capital cost (level at which the decision to proceed with the investments is made) was increased in 15% increments up to 60% above the original estimate. The impact of such cost increases is most pronounced on the price per ton lenders would expect in order to lend to the project. Using 75/25 leverage, eight-year tenor of the credit and a DCR of 1.30 the project could be financeable with the price of \$89.2/ton, if there were no additional capital costs. On the other hand, if capital cost were to rise by 60%, the price required in the first year of operations would have to be \$121.1/ton.

Timing of Borrowing

Fig. 5 reflects typical characteristics of a major project development: low expenditures in early phases with poor confidence level as to final project outcome. It was indicated earlier that loan tenor has a major impact on project economics. Therefore, if an eight-year loan tenor available in the market for the project is assumed, timing of borrowing becomes critical. In most cases, sponsors attempt to secure financing as early as possible in project development. This may be a good practice when credit is easy to obtain and on relatively good terms. In the example, however, eight years from the date of commitment to the final repayment is a maximum, meaning had the sponsors borrowed at the inception of the project development they would have had only four years to amortize the debt. By delaying formal credit commitments and by financing initial construction costs entirely with equity, it is possible not only to substantially

Constant: 1. Debt to Equity Ratio = 75/25

2. Minimum Cash Flow Debt Coverage (DCR) = 1.3

Fig. 3. Impact of different debt structures on price per ton.

Constant: 1. Debt to Equity Ratio = 75/25

2. Minimum Cash Flow Debt Coverage (DCR) = 1.3

Fig. 4. Impact of capital cost increases on price per ton.

Fig. 5. Accuracy of cost estimates vs. engineering progress.

improve cash flow and debt coverages during the critical initial years of operations, but also to improve the economic returns to the project sponsors.

Fig. 6 reflects dramatic improvements in debt coverages using three different debt/equity structures of 25/75, 50/50, and 75/25. The delay of two years in executing bank credit in case of 50/50 leverage allows for two years longer amortization period, which improves debt coverage from 0.94 to 1.24 in the first year of operations. This produces a difference between a project that clearly is not financeable to the one that begins to meet lenders' criteria.

To one's surprise, perhaps, internal rate of return on equity (IRE) (Fig. 7) also increases, although initial expenditures are funded solely by equity. If there is a 75/25 debt/equity structure, IRE improves from 13.57% to 14.23% by deferring commitment and increasing repayment period by two years.

Referring again to Fig. 5, one may surmise that in the early phases of project development there is a great deal of risk. This risk can be reduced by additional engineering studies which, in relation to total project cost, are not that substantial. Obtaining financing too early can penalize the project since lenders will implicitly demand higher DCR, which may result in much tougher credit terms or even denial of credit. However, proper balancing of project developmental work with timing of financing commitments may improve lenders confidence in the project, lower debt coverages, and enhance owners' profitability.

Fig. 6. Impact of postponing debt commitments on DCR.

Fig. 7. Impact of postponing debt commitments on IRE.

Conclusions

The preceding has attempted to highlight how critical financial variables are in planning new projects. The main conclusions are summarized as follows:

1. The sensitivity of project cash flows in relation to fluctuations in leverage, debt structure, or timing of borrowing is typically of major importance.

2. A properly analyzed and structured project financing may require lower debt coverage ratios offering prospects for better credit terms and conditions.

3. Profitability to project sponsors may also improve when financing issues are adequately recognized.

In short, the successful commercial implementation of a project can be brought a step closer by careful assessment of the impact of financing on project economics.

Planning and Design of Surface Mines

Robert Laurich, Editor

5.1 Definition of Mining Parameters

DAVID ARMSTRONG

INTRODUCTION

Many factors govern the size and shape of an open pit. These must be properly understood and used in the planning of any open pit operation. The importance of each will depend on the particular project, but the following are the key items affecting the pit design: geology, grade and localization of the mineralization, extent of the deposit, topography, property boundaries, production rates, bench height, pit slopes, road grades, mining costs, processing costs, metal recovery, marketing considerations, strip ratios, and cutoff grades. This section will discuss several of these factors.

BENCH HEIGHT

The bench height is the vertical distance between each horizontal level of the pit. The elements of a bench are illustrated in Fig. 1. Unless geologic conditions dictate otherwise, all benches should have the same height. The height will depend on the physical characteristics of the deposit; the degree of selectivity required in separating the ore and waste with the loading equipment; the rate of production; the size and type of equipment to meet the production requirements; and the climatic conditions.

The bench height should be set as high as possible within the limits of the size and type of equipment selected for the desired production. The bench should not be so high that it will present safety problems of towering banks of blasted or

unblasted material or of frost slabs in winter. The bench height in open pit mines will normally range from 15 m (49 ft) in large copper mines to as little as 1 m (3.3 ft) in uranium mines.

PIT SLOPES

The slope of the pit wall is one of the major elements affecting the size and shape of the pit. The pit slope helps determine the amount of waste that must be moved to mine the ore. The pit slope is usually expressed in degrees from the horizontal plane.

A pit wall needs to remain stable as long as mining activity is in that area. The stability of the pit walls should be analyzed as carefully as possible. Rock strength, faults, joints, presence of water, and other geologic information are key factors in the evaluation of the proper slope angle. The slope may be stated as a simple, overall average for the pit (e.g., 45°), but a more detailed study may show that the physical characteristics of the deposit cause the pit slope to change with rock type, sector location, elevation, or orientation within the pit. Fig. 2 illustrates how the pit slopes may vary in the deposit.

A proper slope evaluation will give the slopes that allow the pit walls to remain stable. The pit walls should be set as steep as possible to minimize the strip ratio. The pit slope analysis determines the angle to be used between the roads

Fig. 1. Bench cross section.

Fig. 2. Example of pit slopes varying in a deposit.

Fig. 3. Pit designed with a 45° pit slope.

in the pit. The overall pit slope used for design must be flatter to allow for the road system in the ultimate pit.

Figs. 3 and 4 show the need to design the pit with a lesser slope to allow for roads. The pit in Fig. 3 has been designed with a 45° angle for the pit walls. The pit in Fig. 4 uses the same pit bottom and the 45° interramp slope between the roads, but, a road has been added. Note the

larger pit that results. In the example, almost 50% more tonnage must be moved to mine the same pit bottom.

In the early design of a pit a lesser pit slope can be used to allow for the road system. The pit in Fig. 5 was designed with an overall slope of 38°. The overall slope to use will depend on the width, grade, and anticipated placement of the road.

Fig. 4. Pit designed with a 45° interramp slope and a road system.

Fig. 5. Pit designed with a 38° overall slope to allow for a 45° interramp slope and a road system.

Fig. 6 shows a vertical section of a pit wall from Fig. 4. The interramp angle is projected from the pit bottom upward to the original ground surface at point B. The overall pit slope angle is the angle from the toe of the bottom bench to the crest of the top bench. Point A shows the intercept of the overall pit slope angle with the original ground surface.

CUTOFF GRADE

As stated by Taylor (1972), a "cutoff grade is any grade that for any specified reason is used to separate any two courses of action." The reason used in setting a cutoff grade usually incorporates the economic characteristics of the project.

When mining, the operator must make a decision as to whether the next block of material should be mined and processed; mined and stockpiled; mined (to expose ore) and sent to the waste dump; or not mined at all. The grade of the block is used to make this decision.

For any block to be deliberately mined, it must pay for the costs of mining, processing, and marketing. The grade of material that can pay for this but for no stripping is the breakeven mining cutoff grade.

A second cutoff grade can be used for blocks that are below the mining cutoff grade and would not be mined for their own value. These blocks may be mined as waste by deeper ore blocks. The cost of mining these blocks is paid for by the deeper ore. The final destination of these blocks is then only influenced by costs for the blocks once they have been mined. The blocks can be processed at this point if they can pay for just the processing and marketing costs. Because the revenue for the block does not need to cover the mining cost, the milling cutoff grade is lower than the mining cutoff grade.

The cutoff calculation depends on the point of the cutoff decision in the life of the mine. In deciding whether to mine one more block at the end of the mine life, the only costs

Fig. 6. Vertical section through a pit wall.

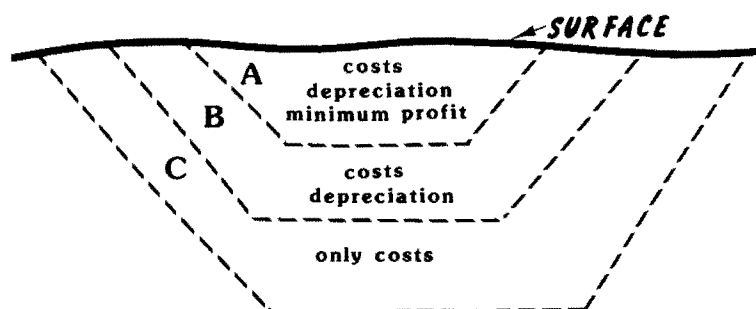

Fig. 7. Relative pit sizes using different levels of costs.

used would be the cash operating costs and a minimum profit to reflect the opportunity costs of using the money elsewhere. For a decision to mine one more year, the costs would be the cash operating costs, plus the replacement capital needed, plus all general and administrative costs that would be incurred.

For a mine in the planning stage, the costs to be used are more complex and must be carefully considered. All direct costs of mining, processing, and marketing should be used. In the mining phase this would include the drilling, blasting, loading, and hauling costs. The processing costs would cover crushing, conveying, grinding, and concentrating costs. Depending on the final form of the product, the marketing costs could include concentrate handling, smelting, refining, and transportation. Additional direct costs for royalties and taxes would also be included.

Overhead costs should also be added to the calculation. The general and administrative costs for the mine, mill, and administrative office staff should be included. Until the size of the pit has been determined and the associated overhead costs developed, the costs to be used for the calculation can only be estimated and are therefore subject to later refinement.

Depreciation is used in the calculation for the purpose of setting the pit size. As shown in Fig. 7, the size of the pit

will increase if the burden of some costs is removed. The cutoff grade is lower in increment C than in increment B. This is due to the lower costs used in determining the cutoff grade.

The material in increment C can only be economically mined after the plant has been depreciated. A plant built to handle the material in increment C would not be justified because the revenue would not cover the cost of the plant. If the plant was fully depreciated by the time increment C was mined, the ore would be worth processing.

A minimum profit can also be used to calculate the cutoff grade. It will further decrease the size of the pit as shown by increment A in Fig. 7. The purpose of adding a minimum profit is twofold: (1) it confirms that a block is ore only if it can be mined and processed at a profit; and (2) it sets an economic limit below which a company would find an alternate investment more attractive.

The amount of minimum profit to be used is a difficult decision. A true profit calculation would include the role of depreciation, depletion, and taxes. At the design stage, these are not known. An approximation can be made by increasing the costs.

Other costs and changes in revenue can be included if they are known. These would include recoveries that vary with the ore grade, mining costs that vary with the distance

Table 1. Calculation of Breakeven Cutoff Grade

or elevation of haulage, and the time lag between stripping the waste from a block of ore and the mining of the ore. These values should only be added if they are well known and the added degree of sophistication is warranted.

Table 1 is the calculation of the mining cutoff grade for a copper project with the following parameters:

30	kt/d (33,000 st pd) of ore mined for 20 years
\$300,000,000	capital cost (including replacement capital)
\$1.00	mining cost per tonne of ore
\$0.95	mining cost per tonne of waste
\$3.00	processing cost per tonne of ore
\$1.00	general and administrative (G&A) cost per tonne of ore
\$0.75	freight, smelter, and refining (FSR) cost per kilogram of copper
85%	overall copper recovery

The results are shown graphically in Fig. 8. Note that the cutoff grade will increase as the costs increase. The difference between the mining cutoff grade and the milling cutoff grade is shown in Fig. 9.

STRIP RATIO

The strip ratio is the ratio of the number of tonnes of waste that must be moved for one tonne of ore to be mined. The results of a pit design will determine the tonnes of waste and ore that the pit contains. The ratio of waste and ore for the design will give the average strip ratio for that pit. This differs from the breakeven strip ratio used to design the pit.

The breakeven strip ratio refers only to the last increment mined along the pit wall. The strip ratio is calculated for the point at which break even occurs and the necessary stripping is paid for by the net value of the ore removed.

The calculation for the breakeven strip ratio (*BESR*) is:

$$BESR = (A - B) / C$$

where:

A = revenue per tonne of ore

B = production cost per tonne of ore (including all costs to the point of sale, excluding stripping)

C = stripping cost per tonne of waste

In certain studies a minimum profit requirement is included in the formula.

$$BESR = [A - (B + D)] / C$$

where:

D = minimum profit per tonne of ore.

Table 2 contains the information for calculating the strip ratio for the example used in calculating the cutoff grade previously. The results are shown graphically in Fig. 10.

5.2 Ultimate Pit Definition

INTRODUCTION

There are probably as many ways of designing an ultimate open pit as there are engineers doing the design work. The methods differ by the size of the deposit, the quantity and quality of the data, the availability of computer assistance, and the assumptions of the engineer.

As the first step for long or short-range planning, the limits of the open pit must be set. The limits define the amount of ore minable, the metal content, and the associated amount of waste to be moved during the life of the operation. The size, geometry, and location of the ultimate pit are important in planning tailings areas, waste dumps, access roads, concentrating plants, and all other surface facilities. Knowledge gained from designing the ultimate pit also aids in guiding future exploration work.

In designing the ultimate pit, the engineer will assign values to the physical and economic parameters discussed in the previous section. The ultimate pit limit will represent the maximum boundary of all material meeting these criteria. The material contained in the pit will meet two objectives.

1. A block will not be mined unless it can pay all costs for its mining, processing, and marketing and for stripping the waste above the block.

2. For conservation of resources, any block meeting the first objective will be included in the pit.

The result of these objectives is the design that will maximize the total profit of the pit based on the physical and economic parameters used. As these parameters change in the future, the pit design may also change. Because the values of the parameters are not uniquely known at the time of design, the engineer may wish to design the pit for a range of values to determine the most important factors and their effect on the ultimate pit limit.

MANUAL DESIGN

The manual method of designing pits involves considerable time and judgment on the part of the engineer. The usual method of manual design starts with the three types of vertical sections shown in Fig. 1:

1. Cross sections spaced at regular intervals parallel to each other and normal to the long axis of the ore body. These will provide most of the pit definition and may number from

Fig. 1. Types of vertical sections used for a manual pit design.

10 to perhaps 30, depending on the size and shape of the deposit and on the information available.

2. A longitudinal section along the long axis of the ore body to help define the pit limits at the ends of the ore body.

3. Radial sections to help define the pit limits at the ends of the ore body.

Each section should show ore grades, surface topography, geology (if needed to set the pit limits), structural controls (if needed to set the pit limits), and any other information that will limit the pit (e.g., ownership boundaries).

The stripping ratio is used to set the pit limits on each section. The pit limits are placed on each section independently using the proper pit slope angle.

The pit limits are placed on the section at a point where the grade of ore can pay for mining the waste above it. When a line for the pit limit has been drawn on the section, the grade of the ore along the line is calculated and the lengths of the ore and waste are measured. The ratio of the waste and ore is calculated and compared to the breakeven stripping ratio for the grade of ore along the pit limit. If the calculated stripping ratio is less than the allowable stripping ratio, the pit limit is expanded. If the calculated stripping ratio is greater, the pit limit is contracted. This process continues on the section until the pit limit is set at a point where the calculated and breakeven stripping ratios are equal.

In Fig. 2, the grade on the right side of the pit was estimated to be 0.6% Cu. At a price of \$2.25 per kg of copper, the breakeven stripping ratio from Fig. 3 is 1.3:1. The line for the pit limit was found using the required pit slope and located at the point that gave a waste:ore ratio of 1.3:1. At the limit

$$\frac{\text{Length of waste (XY)}}{\text{Length of ore (YZ)}} = \frac{1.3}{1}$$

On the left side of the section, the pit limit for the 0.7% Cu grade was similarly determined using a breakeven stripping ratio of 1.7:1. If the grade of the ore changed as the pit limit line was moved, the breakeven stripping ratio to use would also change.

The pit limits are established on the longitudinal section in the same manner with the same stripping ratio curves. The pit limits for the radial section are handled with a different stripping ratio curve, however. As shown in Fig. 4, the cross sections and the longitudinal section represent a slice along the pit wall with the base the same length as the

Fig. 2. Pit limits shown on section.

Fig. 3. Strip ratios for different ore grades and metal prices.

surface intercept. The radial section represents a narrow portion of the pit at the base and a much wider portion at the surface intercept. The allowable stripping ratios must be adjusted downward for the radial sections before the pit limit can be set.

The next step in the manual design is to transfer the pit limits from each section to a single plan map of the deposit. The elevation and location of the pit bottom and the surface intercepts from each section are transferred. If a pit slope change occurred on a section, its position is also transferred.

The resultant plan map will show a very irregular pattern of the elevation and outline of the pit bottom and of the surface intercepts. The bottom must be manually smoothed to conform to the section information.

Starting with the smoothed pit bottom, the engineer will develop the outline for each bench at the point midway between the bench toe and crest. The engineer manually expands the pit from the bottom with the following criteria:

1. The breakeven stripping ratios for adjacent sections may need to be averaged.

2. The allowable pit slopes must be obeyed. If the road system is designed at the same time, the interramp angle is used. If the preliminary design does not show the roads, the outline for the bench midpoints will be based on the flatter overall pit slope that allows for roads.

3. Possible unstable patterns in the pit should be avoided. These would include any bulges into the pit.

4. Simple geometric patterns on each bench make the designing easier.

When the pit plan has been developed, the results should be reviewed to determine if the breakeven stripping ratios have been satisfied. The pit can be divided into sectors on the pit plan and each sector checked for the waste:ore ratio. Two ways the stripping ratios for each sector can be checked are:

1. The pit limits from the pit plan maps can be transferred back to the sections and the stripping ratio can then be calculated from the sections.

2. The bench outlines can be transferred to each individual bench map. The ore and waste lengths are measured along the bench outline for each sector. The results for each bench are combined to calculate the stripping ratio for that sector. The ore grade for the sector is the weighted average (by length) of the grade of the ore along the pit limit for each bench.

The total reserves for the pit and the average stripping ratio are determined by accumulating the values from each bench. On each bench the ore tonnes above the breakeven cutoff grade are measured and the average grade of the ore is calculated. The tonnes of waste are also measured. The total of the tonnes of ore and the total of the tonnes of waste on each bench give the average stripping ratio for the pit.

COMPUTER METHODS

As should be appreciated, the manual design of a pit gets the planning engineer closely involved with the design and increases the engineer's knowledge of the deposit. The procedure is cumbersome, though, and is difficult to use on large or complex deposits. Because of the lengthiness of the procedure, the number of alternatives that can be examined is limited. As more information is gathered or if any of the design parameters change, the entire process may have to be repeated. Another drawback to the method of manual design is that the pit may be well designed on each section, but,

Fig. 4. Segments influenced by vertical sections.

when the sections are joined and the pit is smoothed, the result may not yield the best overall pit.

The growth of computer usage has allowed engineers to handle greater amounts of data and to examine more pit alternatives than with manual methods. The computer has proved to be an excellent tool for storing, retrieving, processing, and displaying data from mining projects. Computer applications have been developed to take much of the burden of pit design from the engineer.

The computer efforts can be divided into two groupings:

1. Computer-assisted methods. The calculations are done by the computer under the direct guidance of the engineer. The computer does not do the entire design but only does the brunt of the calculation work with the engineer controlling the process. Examples would be the two-dimensional Lerchs-Grossman technique and the three-dimensional design using an incremental pit expansion method.

2. Automated methods. These are capable of designing the ultimate pit for a given set of economic and physical constraints without intervention by the engineer. One category of automated methods contains the mathematically optimal techniques using linear programming, dynamic programming, or network flows. A second category has the heuristic methods, such as the floating cone method that produces an acceptable pit, but not necessarily an optimal one. As the cost of computer processing decreases, better automated methods will be forthcoming.

Another characteristic differentiating the types of computerized methods is the use of either a whole or partial block for mining. In a whole block method, each block is mined either as a unit or left intact; in a partial block method, a portion of each block can be mined. Each type has certain advantages:

1. *Accuracy*—With the use of partial blocks, the tonnage of small volumes can be calculated quite accurately. The overall tonnage of the pit may be accurate using a whole block method, but, the accuracy is less for smaller volumes.

2. *Physical constraints*—The desired pit slopes and pit boundaries are approximated by the mined blocks. The use of whole blocks may result in pit walls that are unacceptable in terms of operations and slope stability. Some whole block techniques may assume the block size is a function of the pit slope and some may not allow the slope to vary in the pit. Smoothing is usually required for an ultimate pit designed using whole blocks.

3. *Cost*—When properly used, whole block methods have generally proven to be less costly in terms of computer costs than partial block methods. As a result, several pit configurations can be quickly analyzed with a whole block method to give a good basis for a more detailed partial block analysis.

LERCHS-GROSSMAN METHOD

The two-dimensional Lerchs-Grossman method will design on a vertical section the pit outline giving the maximum net profit. The method is appealing because it eliminates the trial-and-error process of manually designing the pit on each section. The method is also convenient for computer processing.

Like the manual method, the Lerchs-Grossman method designs the pit on vertical sections. The results must still be transferred to a pit plan map and manually smoothed and checked. Even though the pit is optimal on each section, the ultimate pit resulting from the smoothing is probably not optimal.

The example in Fig. 5 represents a vertical section through a block model of the deposit. Each square represents the net value of a block if it were independently mined and processed. Blocks with a positive net value have been shaded in the figure. The block size has been set in the example so that the pit profile will move up or down only one block at most as it moves sideways.

Step 1

Add the values down each column of blocks and enter these numbers into the corresponding blocks in Fig. 6. This is the upper value in each block of Fig. 6 and represents the cumulative value of the material from each block to the surface.

Step 2

Start with the top block in the left column and work down each column. Put an arrow in the block pointing to the highest value in:

1. the block one to the left and one above,
2. the block one to the left,
3. the block one to the left and one below.

Calculate the bottom value for the block by adding the top value to the bottom value of the block the arrow points to. The bottom value in each block represents the total net value of the material in the block, the blocks in the column, and the blocks in the pit profile to the left of the block. Blocks marked with an X cannot be mined unless more columns are added.

Step 3

Scan the top row for the maximum total value. This is the total net return of the optimal pit. For the example, the optimal pit would have a value of \$13. Trace the arrows back to get the outline of the pit. Fig. 7 shows the pit outlined on the section. Note that even though the block on row 6 at column 6 has the highest net value in the deposit it is not in the pit. To mine it would lower the value of the pit.

INCREMENTAL PIT EXPANSION

The incremental pit expansion technique is a trial-and-error process guided by the engineer. Although this method will not necessarily produce an optimal pit, in the hands of a skillful engineer it is a very powerful tool. Either whole or partial blocks can be used.

The engineer will digitize the outline of a new pit bottom or an expansion to a pit wall. The computer projects this shape upwards in conformance with the pit slopes to be used. The resulting expansion should be graphically shown to the engineer for confirmation that the increment is as expected.

If the expansion is agreeable to the engineer, a tabulation is done for the material in the increment. The shape of the expansion at the midpoint of each bench is used with the block values for the bench to calculate the grade, tonnes of ore, tonnes of waste, revenues, and costs of the increment. If the increment meets the criteria of the engineer, it is kept in the pit and another outline is digitized. In this manner, the size of the pit gradually grows as the engineer outlines each increment and decides if it meets the design criteria.

To be most effective, the design should progress from the upper benches downward and from the higher grade areas outward on each bench. This is to ensure that only those blocks that can pay for themselves will be included in the pit.

FLOATING CONE METHOD

The most popular automated method has been the floating cone method. The concept is similar to the incremental pit expansion but the manual intervention can be minimized or eliminated.

Instead of a digitized bottom, one block or a group of blocks forms the base of the expansion. If the grade of the base is above the mining cutoff grade, the expansion is projected upward to the top level of the model as in Fig. 8. The

resulting cone is formed using the appropriate pit slope angles.

All blocks that are encompassed by the cone (and are not considered previously mined) are tabulated for the costs of mining and processing and for the revenues derived from the ore. If the total revenues are greater than the total costs for the blocks in the cone, the cone has a positive net value and is economic to mine. The surface topography is then altered to reflect the simulated mining of the cone. The topography is left unchanged unless the cone value is positive.

A second block is then examined, as shown in Fig. 9. Assuming the first cone had a positive value and was included in the pit, only the blocks in the shaded portion need be tabulated.

Fig. 8. Cone centered on a base block.

Fig. 9. Cone formed by a second base block.

Each block in the deposit is examined in turn as a base block of a cone. For a large model, this can be a costly process. The resulting pit is also dependent on the pattern in which the next base block is chosen. For example, a base block on an upper level may not have been economic when initially examined. If part of the waste covering it is stripped by mining a cone from a lower level, the block should again be checked before another block from a lower level is used as a base block. This is necessary to make each cone pay for itself.

Because of this potential problem, an engineer can intervene in the process. The engineer can define a smaller volume in which all base blocks will be checked by the computer. From the results of the cones in this smaller volume, the engineer can specify another volume to check. With this added control, the selection sequence of base blocks is less of a problem.

5.3 Open Pit Optimization

JEFF WHITTLE

INTRODUCTION

Computer hardware, and to a lesser extent software, has for the last 20 years consistently advanced at a rate which has exceeded all expectations. As a result, calculations which were difficult or impossible to do only a few years ago can now easily be completed on a computer small enough to fit on a desk and costing only a few months' salary. What is more, the calculations can be done by users with very little knowledge of computers.

Pit optimization is a field which has benefitted greatly from this process in recent years, and we can now go far beyond simple optimization of a pit outline. Thorough sensitivity work, which has often only received lip service in the past, can now be carried out routinely on every ore body that is examined. Management can be offered the real possibility of trading profit for reduced corporate risk in an explicit manner.

Pit optimization was touched upon briefly in the previous section, but we will now go into it in much more detail and describe what can be done at the time of writing (early 1990). There will undoubtedly be further developments.

THE MEANING OF PIT OPTIMIZATION

The first thing to realize is that any feasible pit outline has a dollar value which can, in theory, be calculated.

By feasible, here, we mean that no wall slope is steeper than the rock can support after allowing for the insertion of haul roads and safety berms. That is, we are talking about overall pit slopes.

To calculate the dollar value we must decide on a mining sequence and then conceptually mine out the pit, progressively accumulating the revenues and costs as we go. If we wish to allow for the time value of money—that is the fact that a dollar we receive today is more valuable than one that we (might) receive next year—then we must discount the revenues and costs by a factor which increases with time.

The second thing to realize is that in doing this calculation we have, in effect, allocated a value to every cubic meter or to every block of rock. What is more, we have allocated these values without taking any account of the mining which has gone before, except that the value may depend on the position

of the block and the effect that its position has on haulage distances.

Current computer optimization techniques attempt to find the feasible pit outline which has the maximum total dollar value. The good ones guarantee that there is no single block or combination of blocks which can be added to or subtracted from the outline to produce an increase in total outline value. That is, they guarantee the absolute mathematical maximum. They also exclude any block combinations which have a zero value.

Once we have fixed the block values and the slopes, we have fixed the optimal outline, and it is important to make the point that there is only one optimal outline. If we assume that there are two outlines of the same value, then it is easy to show that the two taken together would produce an outline of higher value. Consequently the assumption of the existence of two different optimal outlines of equal value is false.

If the block values increase then, in general, the optimal pit gets bigger. If the slopes increase then, in general, the optimal pit gets deeper.

Of course, we have to know the pit outline in order to calculate the values of the blocks, particularly if the time value of money is important. Conversely, we have to know the block values in order to find the optimal outline. We therefore have a chicken and egg situation, and we will return to this.

A SIMPLE EXAMPLE

Let us assume that we have a flat topography and a vertical rectangular ore body of constant grade as is shown in Fig. 1. Let us further assume that the ore body is sufficiently long in strike for end effects to be ignored. Under these circumstances, we only have to concern ourselves with a section.

In this simplified case there are eight possible pit outlines that we can consider, and the tonnages for these outlines are given in Table 1.

If we assume that ore is worth \$2.00 per tonne after all mining and processing costs have been paid, and that waste costs \$1.00 per tonne to remove, then we obtain the values shown in Table 2 for the possible pit outlines.

When plotted against pit tonnage, these values produce the graph in Fig. 2. With these very simple assumptions the outline with the highest value is number five.

There are other things that we can learn from this curve.

Fig. 1. Simplified ore body.

Table 1. Tonnages for the Possible Pit Outlines

Pit	Ore	Waste	Total
1	500	100	600
2	1000	400	1400
3	1500	900	2400
4	2000	1600	3600
5	2500	2500	5000
6	3000	3600	6600
7	3500	4900	8400
8	4000	6400	10400

Fig. 2. Relationship between pit tonnage and value.

Firstly, outlines four and six have values which are close to that of outline five, and this is not just an artefact of this particular ore body. For any continuous ore body, as the pit is expanded towards optimality, the last shell which is added will have only a small positive value. If it had a large one, there would probably be another positive shell to follow. This means that in this case, and in the vast majority of real ore bodies, the curve of value against tonnage is smooth and surprisingly flat at the peak. It is common to find that a 10% range of pit tonnage covers only a 1% range of pit value. The trick is to find the peak, and good optimizers guarantee to do this.

Secondly, consider Fig. 3. If we are working without an optimizer and doing a detailed design for a realistically complex ore body, then we might be working away from the peak at 'A', where changes in pit tonnage can have a significant effect on the value of the pit. In fact, generations of mining engineers have learned that a series of small adjustments, involving a great deal of work, can significantly affect the profitability of the mine. Contrast this with starting from an optimized outline at 'B'. From this point, providing that ore and waste are kept in step with each other, it is difficult to go wrong. Certainly there is no need to experiment with small adjustments. Since, with modern software, we can plot this graph for real ore bodies, we can actually find out how much freedom of movement we have before we start the detailed design. In other words, designs based on optimized outlines are very much easier to do.

THE EFFECTS OF SCHEDULING ON THE OPTIMAL OUTLINE

When we schedule a pit, we plan the sequence in which various parts of it will be mined and the time interval in which each is to be mined. This affects the value of the mine

Table 2. Values of the pits if ore is worth \$2 per tonne and if waste costs \$1 per tonne.

Pit	Value
1	900
2	1600
3	2100
4	2400
5	2500
6	2400
7	2100
8	1600

Fig. 3. The effect of small design changes at different points on the tonnage/value curve.

because it determines when various items of revenue and expenditure will occur. This is important because the dollar we have today is more valuable to us than the dollar that we are going to receive or spend in a year's time. There are various reasons for this:

- Delayed revenue may increase our need to borrow funds and pay interest, thus reducing the effective revenue;
- Delayed revenue may not eventuate—one of the risk factors;
- Delayed expenditure may reduce our need to borrow funds and pay interest, thus reducing the effective expenditure;
- Something unexpected may go wrong with the operation—another risk factor; etc.

The standard way to allow for this is to discount next year's dollar by a certain percentage and to apply that idea cumulatively into the future. Thus we discount future revenues and costs by a particular discount rate and reduce them all to a net present value.

There are two discount rates. The **notional** discount rate is applied to actual revenues and costs which are likely to occur. That is, revenues and costs which follow the inflation rate. Thus the notional rate (typically 20%) includes an allowance for inflation. It is correct to use this, provided that we inflate our revenues and costs for future years. However, we are then in the position of guessing at the future inflation rate and then guessing at a figure to correct for it! It is easier to work out revenues and costs in today's dollars and then to use the **real** discount rate (typically 10%), which does not allow for inflation.

In what we will call **worst case** mining, each bench is mined completely before the next bench is started. Waste at the top of the outer shells is mined early, and the cost is discounted less than the revenue from the corresponding ore which is mined much later. This can make the outer shells uneconomic. The optimal pit for worst case mining is thus generally smaller than is indicated by simple optimization using today's costs and revenues. This can easily be seen by referring to Fig. 1.

In what we will call **best case** mining, each shell is mined in turn and thus the related ore and waste is mined in approximately the same time period. In this case, the optimal pit is usually close to the one obtained by simple optimization. Unfortunately, if we try to mine each shell separately, mining costs usually increase and cancel out some of the gains.

In small pits, worst case mining may be the only possibility. The larger the pit, the more opportunity there is for creative sequencing, and the closer it is possible to get to best case mining.

PRODUCTION OF A DETAILED DESIGN FROM AN OPTIMAL OUTLINE

The precise method used in creating a detailed pit design depends on the tools which are available. It may be done entirely by hand, or with varying degrees of computer assistance.

Whatever the method, the aim is to produce a detailed design which deviates as little as possible from the outline provided by optimization. Where deviation is unavoidable, we try to balance extra tonnage in one place with reduced tonnage in another. The resultant design should in most cases contain ore and waste tonnages very similar to those contained by the optimal outline. If it is not possible to achieve this, then it may be that the slopes were not set correctly for the optimization. For example, insufficient allowance may have been made for the effect of haul roads.

While all reasonable steps should be made to follow the optimal outline, the shape of the graph shown in Fig. 2 should be borne in mind. Provided that waste is not included without the ore which it uncovers, small deviations from the outline have little or no effect on the pit value. A useful concept is to say that the spirit of the outline should be followed rather than the detail. Certainly the square edges of the blocks on the outer surface of the outline are irrelevant. As a starting point, a smooth line should be drawn through them as is shown in Fig. 4. Remember that the block edges are artefacts, they do not represent geological or grade boundaries.

The achievement of the necessary minimum mining widths at the bottom of the pit is often cited as a problem with pit optimization. This problem is more apparent than real in that, for large disseminated or near horizontal ore bodies, the necessary adjustments at the bottom of the pit are usually easy, whereas, for steeply dipping reef structures, it may be possible to put extra constraints into the optimization so as to ensure the necessary width. In the remaining cases, some loss of pit value will be involved in adjusting the bottom of the pit, but it should never exceed 1 or 2%.

THE AVAILABLE OPTIMIZATION METHODS

All currently available methods of optimization attempt to find the optimal outline in terms of a block model. That is, they try to find the list of blocks which has the maximum total value while still obeying the slope constraints.

The enormity of this problem is seldom appreciated.

Trial and Error

Consider a trivial model with only one section and 10 benches of 10 blocks. If we take a very simple-minded approach, each of the 100 blocks can either be mined or not, so there are 2^{100} or 10^{30} alternatives, many of them not feasible. Even if a computer could assess a million alternatives a second, it would still take three million times the current age of the universe to find the best one!

Fig. 4. Smoothing out the block outline.

If the allowable slope is one block up or down at each column change, and we use this information to ensure that we try only feasible alternatives, the number of alternatives is reduced to 10×3^9 or 200,000. A computer could easily assess this number of alternatives. However, if we extend the model to 10 sections, the number of alternatives rises to 10×2^{99} or about 10^{30} again, and we still have only 1000 blocks, which is insufficient for serious work.

Put simply, trial and error is useless.

Floating Cone

The floating cone method has been popular because it is easy to program and easy to understand. It works by searching through the block model for ore blocks and then assessing the value of the inverted cones which have to be mined to expose them. If the value of a cone is positive, it is mined out and all the blocks it includes are changed to air blocks. The search then continues.

Unfortunately, this simple-minded approach rarely finds the optimal pit because of two distinct problems; one causes it to omit profitable ore from the pit and the other causes it to include non-profitable ore.

The first occurs because it cannot try all possible combinations of ore blocks, as that would be a trial and error process, and we have seen that that is computationally unreasonable. Most pits are viable in part at least because numbers of ore blocks combine to pay for the stripping of waste above them, when no individual block or even close group of blocks can do so. The floating cone method cannot detect this co-operation between different parts of the ore body if neither part is viable in its own right.

The second occurs for slightly more technical reasons. In Fig. 5 there are three small ore bodies and their corresponding waste volumes, with their values and costs shown. A floating cone program will examine A and will find that the corresponding cone has a total value of $(40 - 20 - 30) = -10$, and so is not worth mining. It will then examine B, will find a cone of value $(200 - 80 - 30) = +90$ and will convert it to air, leaving the values shown in Fig. 6.

If a floating cone program is to work correctly, whenever it converts a cone to air, it should start searching again at the top of the model. However, this is computationally very expensive so that most programs continue their search downwards and would consider C next.

At this time the cone for C has a total value of $(40 - 50 + 40 - 20) = +10$, so that the program mines it. This should not happen, because some of the value of ore body A is being used to help pay for the mining of waste

Fig. 5. Ore and waste values before floating cone run.

Fig. 6. Ore and waste values after the removal of ore body B and its corresponding waste.

(the -50 region) which is below it. The true optimal pit in this case includes A and B, but not C.

Apart from being easy to understand and program, the one advantage that the floating cone method has over other methods is that, if instead of using just one block the program uses a disk of blocks as its starting point, then this can ensure a particular minimum mining width at the bottom of the pit.

Two-Dimensional Lerchs-Grossmann Method

In 1965 Lerchs and Grossmann gave two different methods for open pit optimization in the same paper. One works on a single section at a time. It only handles slopes which are one block up or down and one across, so that the block proportions have to be chosen so as to create the required slopes. This method is easy to program and is reliable in what it does, but, since sections are optimized independently, there is no guarantee that successive sections can be joined up in a feasible manner. Consequently a good deal of manual adjustment is usually required to produce a detailed design. The end result is erratic and unlikely to be truly optimal.

Two later variants of this method exist. One (Johnson, Sharp, 1971) uses the two-dimensional method both along sections and across them, in an attempt to join them up. The other (Koenigsberg, 1982) uses a similar idea but works in both directions at once. Both are restricted to slopes which are defined by the block proportions and neither honors even these slopes at 45° to section. This last point is best illustrated by running the programs on a model which contains only one (very valuable) ore block. The resulting pit is diamond shaped rather than circular, with slopes correct in the E-W and N-S directions, but much too steep in between.

Three-Dimensional Lerchs-Grossmann and Network Flow

The second method given by Lerchs and Grossmann (1965) was based on a graph theory method, and Johnson (1968) published a network flow method of optimizing a pit. Both guarantee to find the optimum in three dimensions regardless of block proportions. Both, naturally, give the same result.

Both are difficult to program for a production environment where there are large numbers of blocks. Nevertheless this has been achieved and programs are now available which

can run on any computer from a PC upwards. Most of these use the Lerchs-Grossmann method.

Because these programs guarantee to find the sub-set of blocks with the absolute maximum value consistent with the slope constraints, the alterations to the pit outline caused by small slope or block value changes are reliable indicators of the effect of such changes. This has opened up the field of real sensitivity analysis, where the effects of slope, price and cost changes can be measured accurately. With other methods, only the crudest sensitivity work is possible.

This has led to the development of programs which automate some aspects of sensitivity analysis to the point where graphs of net present value against, say, total pit tonnage, can easily be plotted. Further mention of this will be made later.

CALCULATING BLOCK VALUES

The correct calculation of block values is essential for any optimization. If the block values are wrong, the optimized pit outline will also be wrong.

For optimization purposes, there are two basic rules which must be followed when calculating the value of a block.

The First Rule

Calculate the block value on the assumption that it **HAS** been uncovered and that it **WILL** be mined.

No allowance for assumed stripping ratios should be made, because stripping is precisely what pit optimization works out. If a stripping ratio is assumed when calculating the block values, the result of the optimization is being prejudged.

Similarly, take no notice of any pre-conceived breakeven cutoff. The use of a breakeven cutoff can be helpful in manual pit design; it is inappropriate for optimized pit design. A consequence of this is that a block model in which only rock containing grades above a breakeven cutoff is designated as ore, is also inappropriate for pit optimization.

The only relevant cutoff in this context is that grade at which the revenue from recovered product will just pay for the cost of processing and any extra mining cost which is only applicable to ore.

Second Rule

Include any on-going cost which would stop if mining were stopped.

This is because, when the optimization program is adding a block to the pit outline, it is effectively extending the life of the mine. It must therefore pay for all the costs involved in extending the life of the mine.

Incremental costs such as fuel costs, wages, etc. must obviously be included in the cost of mining or processing, whichever is involved.

Overhead costs **WHICH WILL STOP IF MINING STOPS** must also be included. If the mine throughput is to be limited by the overall mining capacity, then these overheads should be included in the mining costs. If the throughput is to be limited by the processing capacity, then these overheads should be included in the processing cost, because only the addition of an ore block extends the life of the mine.

Nonrecoverable upfront costs, such as the cost of building access roads, should not be included in the costs used in optimization. Although these may be paid for with a loan which is to be repaid over a number of years, these repayments will be required whether mining continues or not. If the value of the optimized pit is less than the nonrecoverable upfront costs, then the mine should not be proceeded with.

BLOCK SIZES

There are four block sizes which are relevant in this work.

For Outlining the Ore Body

The size of the block that is needed for outlining the ore body depends on the shape and size of the ore body and on the particular computer modelling package that is being used. It may be quite small, which can lead to a model consisting of millions of blocks.

For Calculating Block Values

The value of blocks should be calculated with a block size which is similar to the selective mining size. That is, a parcel of rock should not be so small that it could not be mined separately, nor so large that grades are artificially smoothed. This block is sometimes bigger than that needed for outlining the ore body, requiring blocks to be combined and their grades averaged.

For Designing a Pit

There is now considerable experience in pit design using optimization techniques and, assuming that the pit occupies most of the width and length of the model and that the outline is not too convoluted, then a full model of 100,000 to 200,000 blocks is usually more than sufficient for pit design purposes. This leads to a block size which may be bigger than that for calculating values.

If it is necessary to re-block the value model, then it should be done by adding component block values and **NOT** by averaging grades.

For Sensitivity Work

If we want to do a series of optimizations using, say, different product prices so as to plot a graph of pit value against price, a model of 20,000 to 50,000 blocks will give just the same shape of graph with a very small shift of absolute value. Thus, most optimizations for sensitivity work can be done very quickly and this approach generally leads to a much more thorough sensitivity analysis.

Again, re-blocking should be done by adding values and not by averaging grades.

SENSITIVITY WORK

Although an optimized block outline and the corresponding detailed design are not the same, they do have a close relationship and, provided a good optimizer is used, are very similar in value. Consequently, when comparing two designs, the difference in value between the two optimal block outlines will be very similar to the difference in value between the two detailed designs. This means that sensitivity work can be carried out without doing any detailed designs at all.

Also, because a good optimizer produces a result which is objective and single-valued, it is quite reasonable to take note of small value differences due to, say, changing the slopes by a few degrees. This is not true when designs are done by hand, because an engineer will probably produce different designs on different days, without any change of slope.

During sensitivity work, we explore the economic and slope sensitivity of the mine. We sort out the general scale of mining and hence the operating costs. We decide approximately where the haul roads are to go and adjust the slopes in these regions to the average slope.

This requires a large number of quick optimization runs. However, it is probably the most valuable part of the whole design exercise because it inevitably leads to a much better understanding of the ore body and its economics. Graphs can be prepared which show how various characteristics of the mine, such as value or tonnage, are related to product price, costs, etc.

Probably the most significant graph is the one shown in Fig. 7. This relates net present value (NPV) to total pit tonnage for a given throughput and product price.

First, a set of optimal outlines is prepared, where each is optimal for a different product price. For some fixed product price, each of the outlines is then scheduled as though it was to be the limiting pit. If an automated practical scheduling scheme is available, it should be used. In producing Fig. 7, two limiting schedules have been used. Best case

Fig. 7. Undiscounted, best case, and worst case NPV plotted against pit tonnage.

scheduling involves mining with many small pushbacks or cutbacks. Although in no sense a practical schedule, it indicates the highest possible NPV. Worst case scheduling involves completing the mining of each bench before starting the next. This is usually practical, but produces the lowest possible NPV.

The NPV for any practical mining schedule must lie somewhere between the two lower curves, with smaller pits tending towards the bottom curve and larger pits providing opportunities to get nearer to the middle curve.

This graph, which can be plotted for different product prices, is the single-most useful presentation known to the writer. It is meaningful to engineers, accountants, and management alike and can usefully be discussed in committee. It allows profit and corporate risk, in the form of mine life (pit tonnage), to be related and traded explicitly. Once a pit size has been chosen, it is easy to use the corresponding pit outline as a starting point for the detailed design.

This graph can be prepared by using any good optimizer and by doing a lot of work. However, software now exists which will produce the data for it automatically and quickly.

CONCLUSION

We have seen how good pit optimizers can be used not only to help design ultimate pit outlines, but also to carry out sensitivity analysis to an extent which is not possible without them.

Pit optimization is a tool which, used properly, can greatly speed and ease the process of pit design and can significantly increase the value of most pits. It can also be used to reduce the corporate risk involved in mining.

5.4 Optimum Production Scheduling

ERNEST L. BOHNET

The objective of production scheduling is to maximize the net present value and return on investment that can be derived from the extraction, concentration, and sale of some commodity from an ore deposit. The method and sequence of extraction, and the cutoff grade and production strategy will be affected by the following primary factors:

1. Location and distribution of the ore in respect to topography and elevation;
2. Mineral types, physical characteristics, and grade/tonnage distribution;
3. Direct operating expenses associated with mining, processing, and converting the commodity into a salable form;
4. Initial and replacement capital costs needed to commence and maintain the operation;
5. Indirect costs such as taxes and royalties;
6. Commodity recovery factors and value;
7. Market and capital constraints;
8. Political and environmental considerations.

The procedure used to establish the optimal mining schedule can be divided into three stages. The first defines the extraction order or mining sequence, the second defines a cutoff grade strategy that varies through time and will be optimal for a given set of production parameters, and the third defines which combination of production rates of the mine, mill, and refinery will be optimal, within the limits placed by logistical, financial, marketing, and other constraints.

In order to develop an optimum production schedule, a sequence or extraction order inside of the so-called ultimate pit must first be determined. The extraction sequence depends on two subsets of parameters. The first deals with the strip ratio associated with recovering the ore, the grade of that ore, and the physical location of that ore in respect to availability through time.

The second subset of parameters consists of costs associated with starting and maintaining the whole operation. Direct operating costs can be used to define a breakeven cutoff grade and strip ratio, but the objective of mine planning is to devise a strategy that will optimize the total investment. Operating at breakeven cutoffs and strip ratios is only optimal for the final phase at the end of the mine life.

Before the mine production planning commences, a great deal of work has already been completed in exploration and modeling the deposit. From this work, a number of tentative assumptions have been made, including the most probable mining method and hence, the bench height, type, and approximate size of the loading equipment and the mining selectivity. Other test work and assumptions will also have been made regarding the type of process needed to recover the commodity. These parameters will be used to estimate the most probable range of mining and processing costs.

The design of the mining phases can be accomplished by rough manual approximation after review of the bench plans and cross sections, or analytically by computer techniques. Each method has advantages and disadvantages as applied by an experienced engineer, but the method chosen is determined by the accuracy requirements and available funding. If the study objective is very preliminary, with little basic

data available, then manual methods can be justified. If the study is to be a sound basis for investment and development of the mine, and a great deal of information has been collected, then a very thorough computer analysis is warranted.

Computer designed phases can be determined by feeding the data developed and stored in a computer block model into a set of programs that can be used to calculate an economic phase limit. The objective is to develop three dimensional equal profit potential surfaces throughout the mineral deposit. Each surface has to be sufficiently spaced apart to allow adequate room for mining the slices between the surfaces. Since the distance between equal profit potential surfaces will vary, some manual adjustments will be required, as well as the addition of haul roads out of a phase and if required, access left for the next phase. See Fig. 1.

Manual methods depend on having an experienced engineer review the bench plans and cross sections through the deposit to visually pick out the higher grade targets that have reasonable strip ratios. For example, it would be incorrect to first target high grade areas for mining having very high strip ratios that reduce the net value of the recovered ore below the net value of medium grade ore in another area with much less stripping. The manual method is only a first step estimate and, therefore, it will not be as accurate as a computerized technique.

Computerized pit limit determinations can be made using the 2-D Lerchs-Grossman method, or three-dimensional techniques, such as the floating cone or the 3-D Borgmann pit design method. The results of the last two systems are nearly the same, the difference being that the floating cone is a computerized trial-and-error method while the Borgmann is an analytical method.

The strategy used in developing the computerized pit phases is to use higher costs or lower commodity prices in the initial phase and then, for each successive phase, lower costs or higher commodity prices are used. The net effect of this strategy is that the initial phase will have a high breakeven cutoff grade and high net value per ton of ore mined, and each following phase will have a lower cutoff grade and net value per ton of ore.

The accuracy of the estimated costs, recoveries, and commodity price parameters need only be reasonably precise, since they are only used to determine the location of the ores with the relative highest to lowest net values.

Cost estimates needed for determining the extraction sequence can be broken down into three distinct major categories: (1) costs per ton of material mined; (2) costs per ton of ore treated; and (3) costs per pound of commodity produced.

The costs per ton of material mined include the direct mining costs per ton for the drilling, blasting, loading, hauling, ancillary equipment, and mine general and administrative functions. The cost per ton of the capital and replacement expenditures for mine mobile equipment related to the total material mined is also included because the major mobile mining equipment is consumed in approximate direct proportion to the amount of material handled by the equipment, unlike the major initial capital cost components of the plant and infrastructure. The plant components that are replaced

Fig. 1. Internal pit phases: typical pit cross section.

PHASE I DESIGNED USING A 0.80% COPPER CUTOFF
CONTAINS ORE OF HIGHEST NET VALUE.

PHASE II DESIGNED USING A 0.60% COPPER CUTOFF
CONTAINS ORE OF MEDIUM NET VALUE.

PHASE III DESIGNED USING A 0.30% COPPER CUTOFF
CONTAINS ORE OF THE LOWEST NET VALUE,
AND ORE IN LAST FINITE SLICE IN PIT WALL
CONTAINS ORE OF ZERO NET VALUE.

or repaired are usually included in the operating maintenance costs per ton of ore, and are not related to the total tonnage moved in the mine.

The depreciation cost to cover mobile surface mine equipment purchase and replacement will usually be in the range of \$0.15 to \$0.25 per ton of material mined. The magnitude of the cost will depend on the size, type, and anticipated life of the equipment, the mine production level, the haulage distances, and the work schedule.

The most important reason for including mine mobile equipment depreciation is that the method of producing three-dimensional equal profit surfaces in the ore deposit must consider all relevant costs per ton of material mined. If the equipment depreciation were not included, then the cost per ton of material mined will be understated and the phase design will tend to move out into higher stripping ratio areas. This would not matter if the relative strip ratios were equal in all directions around the pit perimeter, but this is rarely so. In most mineral deposits, there will be areas of high and low strip ratios, so moving too far out into a high strip ratio area will lower the net value of the phase, and the 3-D surface generated will no longer be of equal value.

The significance of this costing philosophy can be realized in mining operations where the direct operating costs per ton of material are low relative to the mine equipment depreciation costs per ton of material.

As an example, compare two surface mining operations, one located in the Philippines, the other in Alaska. The net value of a mining increment in each of the pit walls is compared.

	Philippines	Alaska
Direct mining cost/ton of material	\$0.25	\$0.80
Gross value/ton of ore f.o.b. mine	\$3.00	\$3.00
Indicated breakeven strip ratio	12-1 = 11:1	3.75-1 = 2.75:1

If \$0.20/ton of material is added for mobile mine equipment depreciation: breakeven strip ratio

	5.67:1	2.00:1
% change	48%	27%

In summary, the net value of the ore in an incremental slice has to be sufficient to carry all direct operating costs and the initial and replacement expenditures for mobile mine equipment. If the mine equipment depreciation is not included, areas with a much higher breakeven strip ratio will be incorporated into the mine phase, resulting in an overstatement of the net value of ore derived from those high strip ratio areas in the phase.

The second cost collection area is the cost per ton of ore treated and includes expenditures applied to the ore once it has left the mine area. These costs are not related to the total quantity of material removed from the surface mine, but only applicable to the ore tonnage to be treated. Direct costs applied would be:

1. Extra costs associated with transporting the ore to treatment facilities;
2. Crushing and grinding costs;
3. Concentrating cost; and
4. Overhead costs to cover site and head office administrative and general expenditures as well as marketing, sales, and property management costs.

The third cost category is the expenditures incurred per unit of salable commodity(ies) produced. This would cover the sums spent for concentrate handling and transportation, smelting, and refining, and any royalties or taxes that relate to gross revenues rather than profits.

In addition, a certain amount could be inserted into this category to ensure a minimum profit per pound of salable product.

In order to determine the quantity of salable product, recoveries have to be estimated for the concentrating, smelt-

ing, and refining processes. Recoveries should be based on pilot plant results or on recoveries obtained at mines with similar ores and processes.

Gross revenues are determined from the quantity of salable commodity produced multiplied by a specified commodity price.

There are specific reasons for including some costs and excluding others in the determination of the mining limits. The best manner to justify the inclusion or exclusion of a cost parameter is to first answer the question of what factors are reasonably known or unknown. The quantity of minable ore reserves, the strip ratio, and the associated cost per ton of ore for capital are not known at the commencement of the design. Reasonable estimates can be made as to:

1. Mining cost per ton of material;
2. Mining equipment depreciation or cost of the mining equipment consumed per ton of material mined;
3. Ore treatment costs;
4. General overhead costs per ton of ore;
5. Anticipated recoveries;
6. Direct charges per pound of salable product;
7. Commodity price; and
8. Minimum profit expected per pound of commodity produced.

Using these estimated factors, a breakeven cutoff grade can be determined and the final pit limits and total minable ore reserves determined for the breakeven cutoff grade. From these basic parameters, optimization routines can be applied in order to determine the best extraction sequence.

Table 1 illustrates an example of typical base economic parameters used to determine phase increments in a copper mine. If the values were used without modification, the ultimate pit limits would be determined. Since the objective is to define internal phases of higher net value, either an artificial cost is added to the cost per unit of salable product or the commodity value is lowered.

In selecting the economic parameters governing the size of the first phase, the objective is to establish a phase that contains sufficient ore reserves for about a five-year period. This interval would correspond to the payback period and, therefore, it is important to locate the ore with the highest net value during the initial mining sequence.

For example, to try to design the initial phase, an artificial cost of \$0.50 per pound of copper could be added or subtracted from the commodity price so that the ore cutoff would be raised to 0.80% and only material above this cutoff would be classified as ore and generate funds to pay for the removal of waste. The objective will be to generate a series of phases spaced sufficiently apart for practical mining, commencing with an initial phase that roughly corresponds to the payback period, followed by a series of progressively larger phases out to the ultimate pit boundary. The variations in costs and the number of phases are determined by combining judgment with a trial-and-error method. One computerized technique that can provide guidance in selecting the various phases and economic parameters is the 2-D Lerchs-Grossman method. By selecting a few typical sections through the ore deposit, relatively inexpensive 2-D pit limits can be determined for various economic parameters. These results can then be used to set the variable costs needed to determine the pit limits using 3-D computer techniques.

The preceding discussion has described the method used to define the internal pit phases. This is the first stage in defining the optimum production and cutoff grade strategy. The second step is the determination of the optimum cutoff grade strategy to be used from one phase to the next, for a defined trial production rate. Only cutoff grades equal to, or less than, the cutoff grade for a particular phase can be used for determining the optimum cutoff grade. If an attempt is made to use a higher cutoff grade, the physical shape of the phase will no longer be valid since the pit wall location depended on revenues from a specified amount of ore that

Table 1. Basic Economic Parameters Used to Determine a Sequence of Phases (Copper Mine Example)

a. Direct mining costs per ton of material:	\$0.80
Mobile mining equipment depreciation per ton of material:	\$0.20
Total costs for category (a), per ton of material mined:	\$1.00
b. Ore treatment costs per ton of ore:	\$3.00
General and overhead costs per ton of ore:	\$0.75
Total costs for category (b), per ton of ore processed:	\$3.75
c. Smelting, refining, and transportation costs per lb of copper:	\$0.35
Insurance, property taxes, and royalties per lb of copper:	\$0.05
Total costs for category (c), per lb of copper recovered:	\$0.40
(A minimum profit or variable cost can be added to this total)	
d. Plant, smelting, and refining recoveries:	85% or 0.85
e. Commodity price per lb of copper recovered:	\$1.25
(This value can be varied to expand or contract phases)	
(a) + (b)	
Breakeven cutoff equals: $\frac{2000(d)[(e) - (c)]}{100}$	= 0.33%
(b)	
Internal cutoff grade equals: $\frac{2000(d)[(e) - (c)]}{100}$	= 0.26%

will no longer be available. That is, previous low grade ore blocks will now be waste with negative revenues.

In the situation where low grade rock has to be removed from the pit to expose ore, a lower cutoff grade can be used to determine if that low grade material should be processed. This lower cutoff grade is called the internal cutoff grade and is determined by ignoring the mining cost in the breakeven cutoff grade calculation.

The optimum cutoff grade will usually start at a somewhat higher level than the breakeven cutoff grade and will be reduced in time to equal the internal breakeven cutoff grade. The higher the production level, or for a marginal deposit, the less difference there will be between the optimum and breakeven cutoff grades.

The optimum production level can be determined on a strictly economic basis, but with large ore deposits, other constraints such as mining logistics, marketing, and financing will provide limits.

The best strategy can be determined graphically by varying the production rate and cutoff grade for a number of combinations. Fig. 2 illustrates the results from twelve strategies: three production rates and four cutoff grade alternatives. For example, if three pit phases were determined using breakeven cutoff grades of 0.80, 0.60, and 0.30% copper, then four alternative cutoff grade strategies could be:

Alternative	Cutoff grades used inside of each phase		
	0.80 phase	0.60 phase	0.30 phase
1	0.8	0.6	0.30
2	0.6	0.6	0.30
3	0.45	0.45	0.30
4	0.30	0.30	0.30

These cutoff strategies can then be applied to each of the three alternative production rates.

A second, more rigorous method to determine the best mine/mill/refinery production rate and cutoff strategy is to use the approach presented by K. F. Lane. Lane's method considers the constraints placed on the operation by the mine, mill, and refinery (or market). Utilizing the grade/tonnage curves for each of the phases developed in the previous stage and combining this with the three categories of costs, plus a fixed cost per year, the optimum cutoff grade strategy on a net present value basis can then be determined, for a given set of production parameters of the mine, mill, and refinery (market). This analysis is more accurate than a graphic solution since the program will fluctuate the cutoff grades through time to match the unique physical distribution of the ore in the various increments.

In order to develop a practical extraction sequence using this method, a scheduling program has to be first applied to the phases to define the progressive mining sequence. This allows the program to recognize the internal stripping variations and permits the progressive removal of material from more than one phase simultaneously; it permits prestripping of an outer phase as ore is being drawn from an internal phase.

OPTIMUM INITIAL CUTOFF GRADE

30,000 TPD = 0.78% COPPER
45,000 TPD = 0.59% COPPER
60,000 TPD = 0.56% COPPER

Fig. 2. Graphic solution to maximize NPV (NPV vs. production rate and cutoff grade alternatives).

In order to determine the optimum production capacities of the mine, mill, and refinery that will maximize the net present value, a trial-and-error method is used. Initial capital costs estimates are subtracted from the NPV to allow ranking of the various production rate alternatives.

Lane's method allows the mine planner to readily try more alternatives and complete sensitivity analyses on commodity price, recoveries, and other cost parameters.

The preceding discussion has outlined the procedures that can be used to determine the optimum production schedule and cutoff grade strategy. The completed analysis will serve to guide the engineer in detailing the production schedule for both short and long range plans. In cases where the operation is in existence, the same analysis can be completed so that fluctuations in commodity values and costs can be quantified and the plan altered accordingly to optimize the extraction strategy.

It should be noted that in following through the procedures outlined, the basic pit design should be completed first with few or no constraints. The design can then be modified and the costs resulting from constraints can then be quantified. Constraints may be the number of working faces needed for a particular production rate, waste dump locations, drainage routes, property boundaries, ore delivery points, market capacity, environmental constraints, and the availability of personnel, equipment, and financing.

Designing the best and most practical production schedule for each unique ore deposit is a complex task, and only by using a logical procedure that isolates and provides a solution for one set of variables at a time can a satisfactory and optimum solution be determined.

5.5 Materials Handling Ex-Mine

RONALD G. REED

This section will outline design considerations for the development of a hard rock mine in-pit crushing and conveying system. It is not intended to present detailed information for sizing and designing crushers or conveyors since sufficient textbooks, design manuals, and manufacturer's catalogs cover those topics.

The obvious trend in the nonferrous metals mining industry is toward the mining of lower grade ores at increasing tonnage rates. With the progressive development of larger and more efficient milling equipment and alternative processing techniques the definition of *ore*, *low grade*, and *waste* varies at each operation.

The trend toward larger operations has been forced by changing economic conditions that require the mine to strive to lower costs per unit of product recovered. The primary cost elements that determine the profitability of a project are commodity price, capital cost, and operating expenses such as energy (i.e., electricity, fuel), labor, equipment, maintenance, taxes, and environmental protection measures.

Some of the main characteristics that make each mining project distinctive are the following:

1. Location
2. Topography
3. Size and type of deposit
4. Mineral grades/distribution
5. Weather conditions
6. Excess or lack of water
7. Type and cost of energy available
8. Cost of obtaining trained maintenance and operation personnel

9. Management/company objectives

Therefore, any optimum pit design must take into account both the character of the mine and the economic factors as reflected in the costs to recover each unit of salable product.

In the past, the primary crushing, fine crushing, and mill complex tended to be located in relative close proximity and the majority of the horizontal and vertical travel distances from the ore source to the crushing station was handled by truck haulage. Due to rising fuel and maintenance costs, economic conditions have forced the pit designer to minimize the distance the trucks have to transport the ore, and to bring the primary crusher closer to the source and thus utilize conveyors to perform a much larger proportion of the ore transport requirements.

Data generated from actual installations have shown that properly designed crushing and conveying systems compare to truck haulage systems as follows:

1. Significantly lower operating and maintenance costs.
2. Higher initial capital costs, but with lower present value costs when compared to the life of the operation.
3. Improved foul weather operating conditions.
4. Can provide comparable operating flexibility in certain circumstances.

As a comparative example, a study was performed to determine the capital and operating costs of crushing and conveying of waste material from a bench of elevation 1 220 m (4,000 ft). This location was chosen because of the space needed around a crushing station that would allow

four 155-t (170-st) trucks to dump simultaneously to a two-crusher station.

A weighted average haul distance of 2 880 m (9,450 ft) on an 8% grade was used for comparing the crusher-conveyor cost with the truck haulage expenditures. The use of trucks allows an incremental buildup of the dump and the average dump elevation height was 1 376 m (4,516 ft) in contrast to the final dump height of 1 405 m (4,610 ft), which was used in the crusher-conveyor study.

Using an annual tonnage of 41.73 Mt (46,000,000 st), truck haulage operating costs were calculated:

Haul distance (crusher to dump)	Haul time (minutes)
2 880 m (9,450 ft) of that 1 966 m (6,450 ft) is at 8% with 915 m (3,000 ft) level	15.30

This 2 880 m (9,450-ft) haul distance required a minimum of 14 trucks for haulage. Maintenance and fuel costs amounted to \$0.1694/t (\$0.1537/st). The costs per tonne for the crushing and conveying system were calculated to be \$0.0872/t (\$0.0791/st). The installation charge for the fixed crushing and conveying system composed of two 1.37 by 1.88 m (54- by 74-in.) gyratory crushers, 2 060 m (6,760 ft) of 1 500 mm (60-in.) conveyor, and a tripper and stacker was estimated to cost \$28,000,000.

For this comparison example, the following assumptions were made:

1. Minimum 10-yr plant life with crusher station area accessible during the full plant life.
2. The waste system is part of an expansion to the existing plant, therefore, making a phased start-up of the waste system possible.
3. Trucks purchased by year:

Period	Truck purchases
Preproduction	7
Year 1	6
Year 2	2
Year 3	1
Year 4	3
Total	19

4. Eight-year truck life.
5. Conveying system usable for full plant life. Replacement parts for the conveyors are carried in the operating costs.
6. Straight-line depreciation for five years.

This study is purely hypothetical and may seem somewhat simplistic. Many other factors must be considered for any one operation as mentioned earlier in this section. Table 1 illustrates the economic benefits of an in-pit crushing-conveying system.

This crushing-conveying system as compared to truck haulage has a payback period of a little over three years, and

Table 2. Crusher System Characteristics Desired by Mine Personnel

Gyratory type
Large capacity (2.27-3.63 kt/h, or 2,500-4,000 stph)
Freedom from clogging
Maximum frequency of moves (one/year)
Average frequency of moves (one every two years)
Large feed openings (1.37 m or 54-in. minimum)
Ability to crush rock with compressive strength up to 32.2 kt/m (50,000 psi)
High reliability of system (85%)
Freedom from bridging
Low maintenance cost
All-weather operation (-40 to +50 C or -40 to +120 F, rain, snow)
22 hours/day operation, 350 days/year
Moderate noise
Dust control at transfer points
Operate in a pit with 12-15 m (40-50 ft) bench heights
Ability to move up 10% maximum grades (15 m or 50 ft wide)
Maximum relocation time of two weeks
A surge capacity of 360 t (400 st)
Ideally compatible with trucks or trains
Have a minimum of conveyors (but also contain redundancy where necessary)

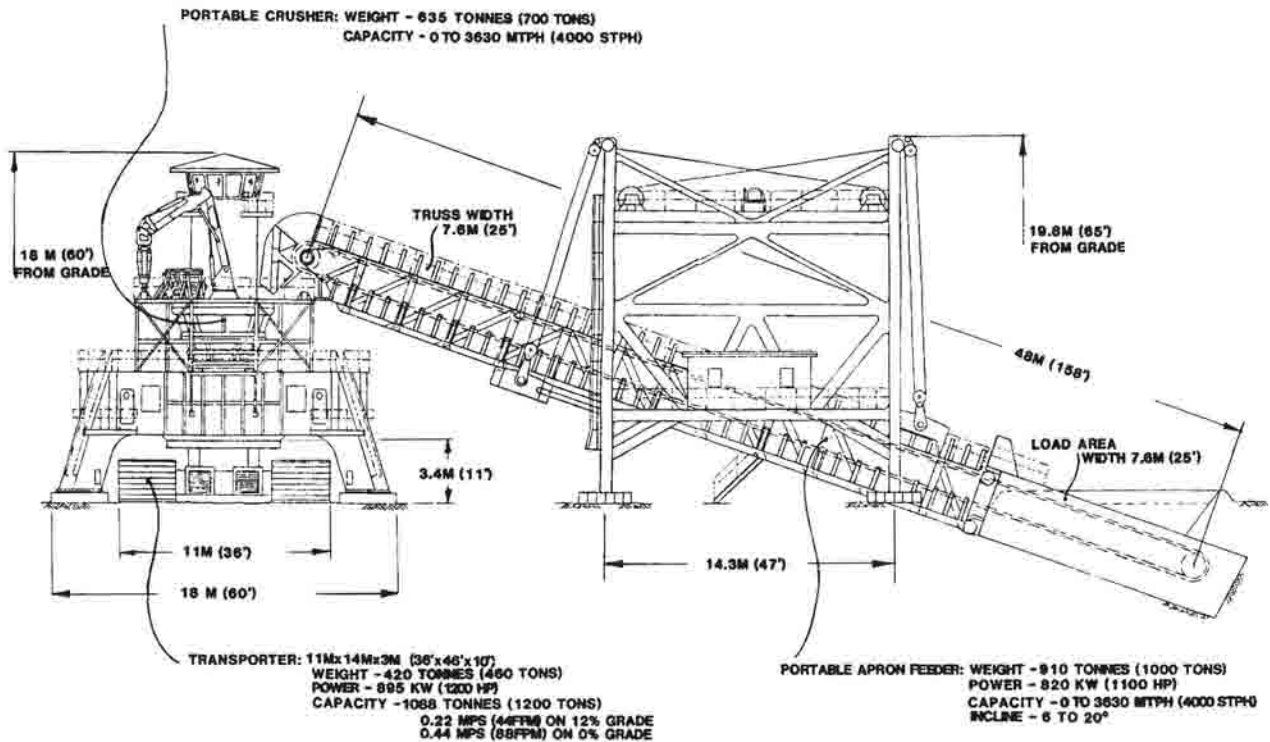

Fig. 1. Portable crusher and feeder at Sierrita mine, Duval Corp.

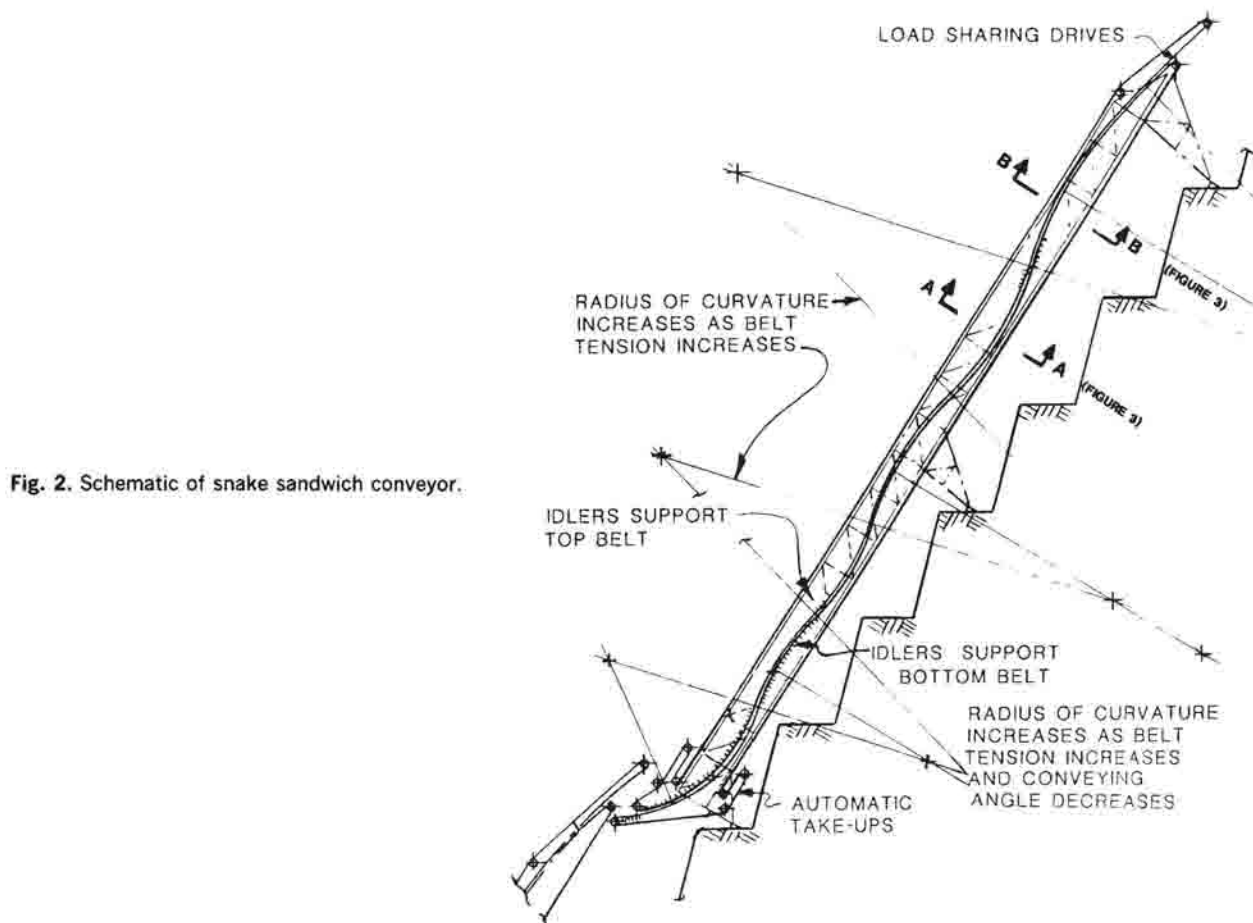

Fig. 2. Schematic of snake sandwich conveyor.

over the 10-yr life has a rate of return of 26.42%. It should be noted that ore usually has to be crushed as preparation for further milling operations. Therefore, the payback for an ore crushing system would be shorter.

With the crushing and conveying system offering potential cost savings, the main drawback is the lack of mobility of the fixed crushing-conveying system.

In certain circumstances with the large tonnages being mined, it can become increasingly difficult to find suitable locations for a fixed crusher/conveying system that will have sufficient longevity to pay for itself.

Mining industry surveys sponsored by the US Bureau of Mines have determined it is difficult to find in-pit crusher locations that are both economically advantageous and that have a useful consecutive life of more than two years. It is obvious that with the dismantling and erection of *permanent systems*, the costs become prohibitive. The studies have also determined that what is needed is a reliable, reasonably priced, *portable* crushing and conveying system. The findings of this survey are listed in Table 2.

As further reported, this system consisting of a crusher, rock breaker, crane, and hopper-feeder would cost between \$6 and 8 million, plus erection costs. This is roughly equivalent to the installed costs of one permanent single crusher.

A system using a 1.52 by 2.26 m (60-in. by 89-in.) gyratory crusher (Fig. 1) has been installed at the Duval Corp.'s Sierrita-Esperanza open pit mine south of Tucson, Arizona. Studies conducted by Sierrita indicate a cost savings of \$0.29 per ton of rock processed by the portable crushing system can be achieved.

The in-pit portable crusher is definitely an alternative worth considering for any large mining operation that has to handle more than 9.1 Mt (10 million st) per year. An in-pit crushing system does have many design considerations that could affect pit production, such as (1) site preparation, (2) alternative ore/waste handling system during crusher downtime, and (3) downtime during system dismantling and re-erection.

Mr. Calvert D. Iles, of Duval Corp., stated, "As a mine becomes more dependent on conveyor haulage, the effects of downtime become increasingly severe." Crusher sites have to be located to minimize the lifts of truck haulage and positioned in the mine plan to minimize moves and possible shutdowns.

The Sierrita in-pit crushing system is made portable by a Dutec (Duval Technology Engineering and Construction Co.) designed transporter. This transporter is capable of moving the apron feeder, crusher, and belt conveyor drive modules. The transporter, measuring 11 m (36 ft) in width and 14 m (46 ft) in length, can handle loads up to 1 088 t (1,200 st) on a 12% grade. The load is kept level when on a ramp by four hydraulic cylinders that adjust automatically.

A mobile 1.37 by 1.89 m (54-in. by 74-in.) gyratory crusher was installed in 1980 at Phosphate Development Corp. Ltd., South Africa (FOSKOR) to crush up to 2 700 t/h (2,950 stph) of run-of-mine ore to 250 mm (-10 in.). (See Table 3.)

Although definite strides are being taken in the technology of in-pit crushing, in-pit conveying is still a problem. With maximum design angles of about 15°, the conveyors still have to be routed around the pit, across roads, and through embankments.

Studies are currently underway to determine what can be done to improve the technology of in-pit belt conveying. Consideration is being given to the loop belt concept by Stephens-Adamson. This method works on the principle that

Table 3. General Specifications of Mobile Crusher (FOSKOR)

Feed hopper capacity	30 m ³
Primary apron feeder	
Width	2.4 m
Length (c-c head and tail sprockets)	23.6 m
Inclination	27°
Conveying speed	0.08-2.4 m/sec through variable speed hydraulic drive
Drive motors	2 × 180 kW hydraulic
Crusher	A.C. 54/74 gyratory with 450-kW drive from 3,300-V power; rated 2 700 t/hr
Crusher Discharge Apron Feed	
Width	2.6 m
Length (c-c head and tail sprockets)	9.2 m
Inclination	15°
Conveying speed	0.3 m/sec
Drive motor	1 × 55 kW
Travel rollers, chain, and drive sprocket are CAT D9. Entire apron feeder can be moved to rear for crusher maintenance.	
Slewing belt conveyor	
Width	1.6 m
Length (c-c head and tail pulleys)	15.0 m
Belt speed	1.5 m/sec
Luffing inclination	0-15°
Max. discharge height	4.5 m
Slewing range	90°
Walking mechanism	
Ground pressure when crushing	200 kPa
walking	240 kPa
Max. gradient (walking)	1:10
Walking speed	1.0 m/min
Length of stride	0.6 m
Lifting cylinders	3 × 400 mm dia
Horizontal stride cylinders	3 × 400 mm dia
Hydraulic pumps	3 × 180 kW
Operating pressure	About 180 bar
Electrical data	
Supply voltage	3,300 V
Crusher motor	3,300 V
Other motors	500 V
Auxiliary transformer	1,000 kVA, 3,300/500 V
Installed power for crushing operation	Approx. 920 kW
walking operation	Approx. 580 kW

depends on the radial forces generated by putting *S* curves in the profile of a *sandwiched* conveyor. By continually varying the curvature, a lift is achieved within "geometrical constraints," conforming to specified mine slopes (see Figs. 2 and 3).

Many high angle conveying concepts have been studied and the sandwich belt conveyor seems the most promising.

CARRYING BELT SUPPORTED
ON 35° TROUGHING IDLERS

SECTION A

COVER BELT SUPPORTED
ON 30° TROUGHING IDLERS

Fig. 3. Scaled representation of belt sandwich and material [1500 mm (60-in.) conveyor].

Tonnages above 907 t/h (1,000 stph) and high lifts of up to 107 m (350 ft) per module should be achieved. A prototype using this method has not yet been made.

It is obvious that the technology of in-pit crushing and conveying is changing. The rapidity of this change depends mainly on economics. These methods may not provide solutions to every open pit mine's current economic problems, but in-pit crushing and conveying methods are becoming significantly more practical and will become more economically attractive in both existing and future surface mining operations.

5.6. Waste Disposal—Planning and Environmental Protection Aspects

ERNEST L. BOHNET AND LUTZ KUNZE

DUMP DESIGN

A waste dump is an area in which a surface mining operation can dispose of low grade and/or barren material that has to be removed from the pit to expose higher grade material. In some instances, material has to be removed for other indirect reasons, such as pit wall stabilization and for haul road construction.

The first step in designing a dump is the selection of a site or sites that will be suitable to handle the volume of waste rock to be removed during the mine's life. Site selection will depend on a number of factors, the most important of which are:

- 1) Pit location and size through time.
- 2) Topography.
- 3) Waste rock volumes by time and source.
- 4) Property boundaries.
- 5) Existing drainage routes.
- 6) Reclamation requirements.
- 7) Foundation conditions.
- 8) Material handling equipment.

All of these parameters will be considered during the site selection process. Once a site or number of alternative locations have been selected, the designing of the dumps can commence, using the same points utilized in defining the best potential dump locations.

The objective of dump planning is to design a series of waste disposal phases that will minimize the horizontal and vertical distances between the source and the disposal area. Since material handling costs are usually the largest single component of the mining cost, well designed dumps play a very important and critical role, affecting the expense of the total operation.

The pit mining sequence and production schedule will be completed prior to dump design with the objective of maximizing the return on the investment. Therefore, two of the most important parameters affecting dump design have been set before any design effort commences: the pit location and size through time and the waste production schedule and source location. These two parameters define where the dumps can start, how fast they will advance, and the ultimate volume that the disposal area must contain. The location where dumping can commence may not necessarily be outside of the pit limits. In some instances, internal dumping may be the most economical and practical method of establishing haul roads to the disposal area or to later pit phases. Also, as an alternative, it may be wiser to dump short and rehandle the material in the future if the economic benefits of this can be demonstrated. This can affect the pit design in the sense that later phases adjacent to the dumps could have higher ratios than the original design. Therefore, these areas should be examined in more detail and the haulage cost savings gained by dumping short compared to the potential ore reserve loss.

The pit mining sequence will define the rate and source of the waste rock. Generally, waste material from upper areas should be hauled to dumps located at higher elevations and lower waste dumped in lower locations. This is common sense if haulage costs are to be minimized. Although this is

the ideal objective, topography, property boundaries, drainage routes, dump stability, environmental considerations, and other constraints may make this objective difficult or impossible to achieve.

Topography will limit the available areas and usually defines the type or shape of the waste dump. More common dump configurations are valley fills (complete or partial), hillside wedges, fan and terraced dumps, and combinations of these. If the pit mining sequence permits backfilling one area that has been depleted while another adjacent area is still active, then this alternative can be preferable instead of extending dumps over virgin areas, depending on haulage and reclamation costs.

Dump areas can also be limited by existing drainage routes and property boundaries. In both of these cases, an economic comparison should be completed to weigh the relative cost and potential savings that would result from removing the constraint, e.g., drainage diversion or property purchase.

Before commencing a dump design, two additional parameters must be determined. The material swell factor and angle of repose are very important factors in determining the dump volume needed and the overall dump slopes. In situ material, when mined, will swell from 10 to 60%, depending on the type of material and fracture frequency. In hard rock operations, the swell factor is commonly between 30 to 45%, meaning that one in situ unit will swell to a volume of 1.30 to 1.45 units.

Loose density tests should be performed to determine the anticipated swell. These figures will first be used to size loading equipment buckets and haul truck box sizes. The second use is to quantify the volume of dumping room that will be necessary to dispose of the material from the mine. Loose material will compact to some degree after placement on the dump. This will depend on the type of material, size distribution, moisture content, disposal method, and the height of the dump. Common compaction numbers will range from 5 to 15%. Crushed and conveyed waste will not have a compaction factor as great as that of waste placed in low lifts by 154-t (170-st) haul trucks.

A second parameter that must be determined is the angle of repose of the loose dump material. Dry run-of-mine rock will usually stand between 34 to 37°. The lower the dump height, the more rapid the advancement and the more irregular the rock pieces, the higher the angle. For design purposes, a conservative slope of 1.5:1 (34°) is recommended in order to safely project the anticipated toe position. Measurements of existing talus slopes will also give a good indication of the expected long-term dump face angle.

The dump configuration will also be affected by the haulage method and by stability and reclamation considerations. The three methods of material handling in order of use are: truck, conveyor, and rail. Truck haulage is used in more instances because of its flexibility and lower capital cost. In particular cases, conveyors are more economical to use for waste disposal with their lower operating costs and where large tonnages have to be transported over either large horizontal or vertical distances. As in-pit mobile crusher development progresses, the tonnages handled by conveying

systems will increase substantially. Rail haulage is in use at only a few of the older surface mining operations and is not considered as an alternative for many future operations.

Stability considerations will affect the design of the dumps either by lowering the ultimate height or reducing the overall slope. The slope can be reduced either by building the dump in lifts or by dozing. Sometimes, a combination of these two methods is necessary for reclamation purposes.

The intermediate phases of a dump may vary to a large extent from the planned final dump configuration. For stability reasons, lower lifts or toe dumps may have to be established during the earlier stages. As the mine life progresses, additional lifts can be placed above the lower dumps, subject to future design criteria. By this, it is meant that the berm left on a lower dump must have a design width to facilitate future reclamation, overall slope reduction for reasons of stability, or leaving sufficient width for an access haul road to a future disposal area.

Mining operations are conducted in many different topographic and climatic conditions. These conditions will require changing the techniques used to safely start and maintain a dump. A high wedge-type dump may be safe in a dry climate if it progresses over a rocky and competent base. The same dump would most likely fail if it progresses over wet hillside soils or permafrost. For this reason, geotechnical studies are very important in predicting the stability of both intermediate and final dump phases. Pertaining to the same situation, dump stability monitoring is also very important in cases where failure has a high probability. The degree of monitoring will depend on the consequences and risk of failure.

Continual monitoring will reduce the risk of injury and equipment damage. Failures are acceptable if this risk can be minimized and the failure will not affect downstream facilities, equipment, and personnel. Some northern operations even use failures as a method of material transport and reclamation, since the failures shorten haul distances and lower the overall dump slope to facilitate reclamation.

Particular emphasis should be placed on drainage in designing both intermediate and final dump phases. Dumps constructed using haul trucks have nearly an impermeable surface so that rainfall or melting snow will pond on the top of the dump or cascade over the face if care is not exercised in the dump design and construction. Dumps should, therefore, be built at a slightly adverse gradient for three reasons:

- 1) Carry runoff away from the crest.
- 2) A positive gradient means that haul trucks will have to power back to the dump crest rather than rolling back. As a safety feature, this will also reduce the chance of parked equipment accidentally rolling toward and over the crest.
- 3) Most mining operations set a speed limit below what a loaded haul truck is capable of achieving. For this reason, a 1 to 2% uphill gradient will not slow haulage, but will increase dump capacity and shorten haul distances.

Waste dumps that progress over or fill up drainage routes must also have special design considerations. If run-of-mine rock is end-dumped from the tip head, then given sufficient dump height, gravity will segregate the larger and smaller fragments. The larger material will roll to the bottom of the dump and will normally form a very permeable base. The finer material gathering in the upper portions of the dump will tend to form a nearly impermeable surface, especially with heavy haulage traffic. Waste dumps built with this natural segregation are free draining and offer little chance of saturation unless the base material weathers rapidly and will have reducing permeabilities through time. The high base

permeability will allow the dumps to progress over small drainage routes and not block the flow. For larger streams, the shifting stresses placed on the base of the dump as it advances can jeopardize any drainage structure, such as a culvert. Therefore, a diversion tunnel is preferable where long-term drainage is critical.

In the case where dump failures occur, a number of corrective procedures can be implemented. These may be as simple as rerouting surface drainage or slowing the rate of advance, or as expensive as modifying the profile and design of the dump. One of the most common methods of stabilizing dump failures and allowing use of the dump to continue is to place more material at or on the toe of the failure. If haulage access to the toe of the dump is not feasible due to elevation differences, then dozers may have to be employed to push material downslope onto the toe. This may be helpful if reclamation regulations require a 2:1 slope for topsoil and revegetation placement.

As a new dump is started in a virgin area, small failures can be anticipated if the dump commences as a wedge type on relatively steep terrain. For this reason, it is better to advance a new dump slowly and not count on all the waste being disposed of at one tip point.

In order to enhance the stability of the initial dump, lower benches may have to be notched into the hillside to key the base of the dump into the slope. It may also be necessary to clear off vegetation, such as trees and brush, and, in some instances, to remove soils and other unconsolidated materials that would not provide a stable dump base if the risk or magnitude of failure was unacceptable.

Another component of dump design deals with operating considerations. If a side hill or contour dump is under construction and a tracked dozer is assigned to the dump, then the tracked dozer can be used to establish a pioneer road in advance of the dump. This road, established at a slightly lower elevation than the dump crest, can be used to collect drainage, act as a level control, give additional dump width, and serve such purposes as a small vehicle and lighting plant parking site. Care must be exercised so the cutting of the pioneer road does not undercut the hillside.

Access to the dumps should be aligned to provide good visibility of the congested area around the dump head. In many instances, the access road will have to be wider than normal to allow it to be used for other purposes, such as a park-up area for mine equipment at the end of a shift, a pull-out area for fueling, a truck weighing station, and for dump lighting. A general rule of thumb is that haul roads should normally be five times the width of the trucks using them. This width would include ditches and berms and allow sufficient room for road maintenance vehicles to work safely while trucks are using the road. Preferably, graders may be able to blade the roads while the haul trucks are using another route, but this is not always possible.

A permanent lighting system can be installed along the route because of the relative long life of most dump access roads and for safety reasons.

The dump width at the tip head should be sufficient to allow for a moderately sized turning circle of the haul trucks. For large trucks, this should be between 61 to 91 m (200 to 300 ft). The length of the active dumping face depends on the number of truck fleets hauling to the area. Commonly, a distance of 30 m (100 ft) should be allowed per loading unit's truck fleet operating to that tip head. High berms should always be maintained along the total dump crest length, except at the tip head where the berm height should be equal to the radius of a haul truck's tire.

A tracked dozer at the dumping point is preferred over a rubber-tired dozer for a number of reasons, including:

- 1) Greater traction that allows it to push more material when the ground is wet or icy.
- 2) The tracks crush larger rock fragments, thereby reducing truck tire damage that occurs at the dumping area.
- 3) A tracked dozer with a winch can free stuck equipment readily.
- 4) A tracked dozer can push material farther over the bank in safety, since traction is spread over a larger area and not at just four points.

In most instances, dump material will not have the same supportive strength as the same material in situ, especially in wet climates. Rolling resistances may increase with traffic to a point of impassibility. Additional thinner lifts of more competent rock may have to be placed on the dump surface to maintain haul roads.

The operating differences between intermediate and final dump configurations can be quite large. For example, the material handling methods may change from truck haulage to crushing and conveying as distances increase. Since the prime objective of dump design is economics, the initial dump should have the shortest haul distance. As the mine progresses, haul distances will become longer and vertical haulage more excessive. Reducing the rate of future material handling cost increases using well-thought-out alternative methods and designs is the objective of good dump planning. Accomplishing this task may mean leaving lower routes open as a future access to potential dump areas if the future discounted savings balances today's cost sacrifice. In rugged terrain, this may mean that lower lifts at the base of a high dump will have to be established early, since later access may be impossible or too costly to construct. Several dumping points of various haulage distances should be available on a daily basis so that when the operation is short of trucks, closer dump points can be utilized to maintain production and when truck availabilities are high, longer hauls can be used.

Climatic conditions coupled with mine locations outside of the United States also will have some bearing on the dump design and operation. Less stringent safety and environmental regulations will allow more economic mine operations.

Politics may also intervene and demand short-term economic savings that will be costly for the operation in the long run.

In comparisons of one design to another, a method should be used that first establishes a base case. Then other designs can be completed and the economic and other advantages and disadvantages weighed.

If a choice exists as to the elevation of the dump, then the preferable order of haulage gradients is level, downhill, and uphill last. If haulage costs are equated to level, -8% downhill and $+8\%$ uphill, then the cost differential for a unit of distance is approximately 1.0, 1.46, and 2.38 for a 154-t (170-st) haul truck. This means that waste dumps should be designed level from the start point and only after the dump has progressed a certain horizontal distance will an upper lift become more economic. As an example, only when the horizontal haul distance exceeds 457 m (1500 ft) will it be more economical to lift the material 15 m (50 ft) and start another lift closer to the pit (see Fig. 1). If a dump were mistakenly designed so that all the volume was dumped from an elevation 15 m (50 ft) higher than necessary, and if 90.7 Mt (100 million st) could have been dumped at the lower elevation first, then the direct cost increase would be approximately \$0.019/t (\$0.017 per st) or a total of \$1,700,000. Additional capital and replacement costs would also be incurred due to the increase in the number of haul units required.

Therefore, it is very important to recognize the best economic dumping plan and material handling method and to weigh the cost and effect of constraints such as stability, reclamation, drainage, and property boundaries.

Waste dump planning is usually not as critical or as detailed as mine design. This is due to the fact that the mine is the source of the ore and revenues. However, good waste dump design can be critical in minimizing costs and increasing the value of the ore produced. Improper waste dump planning can mean the difference between profit and loss and often should receive more attention and detail.

STABILITY OF MINE WASTE DUMPS

The overall stability of mine waste dumps is dependent on a number of factors such as:

- 1) Topography of the dump site.

NOTE: LOCATIONS ① AND ② WOULD HAVE EQUIVALENT HAULAGE COSTS

Fig. 1. Equivalent truck haulage distances.

- 2) Method of construction.
- 3) Geotechnical parameters of the mine waste.
- 4) Geotechnical parameters of the foundation materials.
- 5) External forces acting on the dump.
- 6) Rate of advance of the dump face.

All of these factors combine in various ways during the life of a mine waste dump to aid in the stability of the dump or to contribute to its instability. The various technical analyses used to assess the stability of dumps are well documented in literature (Winterkorn and Fang, 1975; Anon., 1977) and will not be covered in this section. The factors affecting stability mentioned earlier will instead be discussed.

The choice of dump sites and their topography usually is limited to within an economic distance from the mine and, since rearranging of site topography is rare, the topography usually becomes a fixed condition. The crucial aspect of topography is the existing slope of the natural ground upon which the dump is to be constructed. Analyses show that factors of safety begin to drop significantly above a ground surface inclination of 20°, regardless of the strength parameters of either the waste or foundation material.

Mine waste dumps are usually constructed by one of two common methods: in lifts or layers or by end-dumping. End-dumping is a controlled failure process where the waste material is deposited forming a slope at or close to its angle of repose and the factor of safety is accordingly close to one. Since the front face is always advancing during the life of the dump, the slopes are not stabilized by flattening with conventional earthmoving equipment until closure of the dump. Monitoring of the *live* dump face is recommended to anticipate and deal with slope failures. The mine waste dumps constructed using an end-dumping technique are sometimes referred to as "built from the top," whereas, layered dumps are said to be constructed "from the bottom up." Layered dumps can be controlled, which adds significantly to their overall stability; however, they require a relatively gently sloping topography and usually entail a longer haul distance in the early years of the mine. Layered dumps are preferred where weak foundation conditions exist, since the load application can be controlled to allow for strength gains by consolidation and pore pressure dissipation.

The geotechnical properties of the mine waste and the foundation material are major factors in determining the overall stability of a mine waste dump. Such characteristics as strength, friction angle or cohesion, and gradation are parameters determining the type of analyses that would be selected to solve or define the stability condition. Each mine waste dump site presents a unique set of problems and would have to be analyzed as a separate and distinct case; however, certain general conclusions may be drawn based on some simplifying assumptions.

For instance, coarse frictional material on a competent foundation with a slope angle less than or equal to the material's angle of repose may be dumped to practically unlimited heights and would represent the safe side of the problem. Cohesive wastes on a weak foundation that could fail either in the waste material itself or through the foundation by a number of mechanisms would represent the unsafe, unstable side of the problem. Between these extremes exist a large number of combinations that have different failure modes and, therefore, must be carefully analyzed.

The most commonly occurring combinations are coarse frictional materials on weak shallow foundations or weak foundations extending to considerable depth. The failure modes associated with these are horizontal translation of the waste, deep seated rotational shear failure through the foun-

ation, or a combination of the two. For cohesive wastes on shallow or deep, weak foundations, the failure modes become difficult to distinguish and the type of analyses used becomes a matter of experience and judgment. It should be remembered that regardless of the sophisticated analysis and the capacity of computers to produce numbers to several decimal places, the reliability of the calculated factors of safety is dependent primarily on the degree to which the input parameters or assumptions made are representative of the actual conditions existing in the waste material and of the foundation of the dump. This is where an engineer's experience is vital to assess the stability of a mine waste dump by determining whether the assumptions and choice of analyses are reasonable.

External forces, such as water and earthquakes, often play a decisive role in the stability of a mine waste dump and, therefore, should be carefully considered in the analysis. Of the two, earthquake or seismic forces are a relatively straightforward factor that can be readily accommodated in most stability analyses by determining the location of the mine waste dump in relation to seismic zones and inputting the proper seismic coefficient into the analyses as an additional horizontal force.

The effect of water on the stability of mine waste dumps is more difficult to evaluate and, as a general rule of thumb, measures should be taken to prevent water from entering the dump. Water pressure buildup in a dump will always lower the factor of safety and, therefore, should be prevented, if possible.

It is not always possible to avoid building mine waste dumps across drainage courses and, therefore, provisions should be made for unimpeded passage of flows either around the dump by ditching to divert surface waters or by providing a coarse, filter-protected drainage layer beneath the dump. The top surface of the dump should be sloped away from the leading edge of the dump face to eliminate ponding during periods of rainfall and snowmelt. In some instances, it may be necessary to include inclined drainage layers at the perimeter of the dump to maintain drained conditions.

In summary, the stability of mine waste dumps is dependent on a combination of factors and, although sophisticated numerical analyses are available to solve stability problems, practical experience and engineering judgment are still the dominant ingredients needed to arrive at an economical, practical, and safe solution.

MINE RECLAMATION

The purpose of reclamation is to upgrade the physical character of all or part of a mining area after the mineral values have been removed and, thereafter, to protect the surrounding environment from contaminants.

However, restoration differs from reclamation in that it means to recreate the original topography and reestablish the land to its previous use and character.

In surface mining operations, the three largest areas that are reclaimed are the mine excavation, the mine waste dumps, and the mill tailings area. This section pertains to the first two items.

Different types of surface mining operations will tend to facilitate or hamper programs that reclaim both the pit and waste dump area. If the commodity extracted is a bedded deposit of large extent and of relatively shallow depth such as in coal mines or if a number of separate pods of ore are mined from individual pits as in uranium deposits, then backfilling of worked-out areas is a common method of waste

disposal and reclamation. Waste material removed from the initial box cut or pit can either be stockpiled and later transported to fill the final excavation or the stockpile could be reclaimed and not moved and the last pit left with little reclamation effort applied.

However, in most surface operations in commodities other than coal, the amount of backfilling is restricted or totally impractical. Therefore, most of the reclamation effort is directed toward the waste disposal area.

If the mining area must be restored to original topography, then very few operations can afford to accomplish this task. In many instances, new topography can be constructed to be superior to the original. During excavation, the waste material swells from 10 to 60%, depending on the type of material and its size and shape distribution. Therefore, in a coal operation, for example, the amount of coal removed will usually not compensate for the larger volume of waste due to swelling. The net effect is that a greater volume exists after excavation and if used as pit backfill the new level of topography has to be higher than the original, e.g., with strip ratios greater than 3.3:1 and a swell factor of 30%. This can work in reverse when the volume of the minerals removed is greater than the increase in volume obtained from waste rock swell, e.g., strip ratio lower than 3.3:1 and a swell factor of 30%. In coal mine reclamation, it is sometimes mandatory that the backfilled waste be redeposited in the same stratigraphic order. This can further add to the mining complexity and reclamation cost. When a reclamation plan is devised, normally all topsoil from both the pit and dump area has to be removed and stockpiled, and erosion protection methods applied at the beginning of the mining activity. This could be done in phases as the pit and dump areas expand through time. In order to minimize costs, a good plan will reduce double handling so that soils removed from one area can be directly laid down on another area where the mining activity has been completed.

The degree of effort in mine reclamation or restoration will be sensitive to a number of factors including:

- 1) Government regulations.
- 2) Prior land use.
- 3) Proximity to population centers.
- 4) Desired aesthetic value and visibility.
- 5) Quantity and types of airborne or waterborne contaminants that could be released from the excavation and dumps.
- 6) Local vegetation types and densities.
- 7) Climatic conditions.
- 8) Location of mine in respect to state and country.
- 9) Mining company policy.
- 10) Cost and effect on mine development.
- 11) Prior reclamation efforts in the area.
- 12) Dump configuration.
- 13) Type and size distribution of dump material and available soil quantities and quality.
- 14) Natural and introduced fauna species of area.
- 15) Proposed end use of land.
- 16) Availability of water and water-table level.
- 17) Topography.
- 18) Existing and rerouted drainage flows with respect to quantities, flood levels, and frequency.
- 19) Downstream water uses.
- 20) Future potential of currently uneconomic minerals in the waste dumps and mineralization adjacent to the pit excavation.

All of these factors will have to be considered in designing a suitable reclamation plan that will meet with approval from

the mining company, the public, and the designated governing authorities. Each property will be unique in the sense that the factors will have different effects and weights on the cost of the reclamation plan.

In most surface mining operations, the waste material removed from the pit is deposited on an adjacent area. The area required for waste disposal is usually equal to or greater than the pit area because the disturbed waste material has a greater volume than in situ, a lower slope angle than the pit walls, and rarely can the material be stacked as high as the pit is deep. Normally, the first area available for reclamation is a part of the waste dump. If the pit area cannot be economically backfilled, then the reclamation efforts applied to this area will only take place toward the end of the mine's life.

In designing waste dumps, particular consideration has to be given to reclamation needs if the cost is to be minimized. If the overall slope of the dump face has to be reduced to prevent erosion and to allow placement of top soils and vegetation, then the dump design should consider terracing to minimize the amount of material rehandling. As illustrated in Fig. 2, the cost of rehandling decreases in proportion to the square of the reciprocal of the number of terraces into which a dump can be broken. Therefore, a dump constructed using three terraces will have only one-ninth the rehandle dozing costs of a dump of similar height with no terracing. In order to facilitate reclamation efforts, a berm should be left on each terrace level. This will lower costs by providing easier access to the faces for equipment spreading topsoil and for revegetation efforts. The berms can also serve as erosion protection and drainage diversions, if necessary. In order to select the number of terraces, increases in material handling costs due to the increase in the number of lifts cannot be allowed to exceed that saved in reducing reclamation dozing costs.

The main hazards to a reclamation project will be erosion and leakage of contaminated waters that will hamper revegetation or be hazardous to life. Both of these problems usually can be corrected through proper drainage control and treatment. Drainage channels will need to be rock-lined if the channels are to remain in the same location without excessive bank erosion.

The depth of topsoil spread on the waste disposal areas will depend to a large extent on the amount that is available. A desirable thickness would be 0.6 m (2 ft) or greater and, to a large extent, will depend on reclamation regulations pertaining to the area. In no case should it exceed the current depth of soil cover.

Reclamation of large, deep open pits is very limited if the pits cannot be backfilled. Typical reclamation efforts in these cases would be to allow the pit to fill with water. This area then could be used for recreational purposes such as fishing or as a water reservoir. The pit crest can be blasted and dozed into the excavation to create a more gentle slope along the edge of the water. This will facilitate water access and will provide a more suitable area for vegetation regrowth and waterfowl habitat. Care has to be exercised using this technique if the chance of bank failure is increased. Pit walls that extend a large distance above the water level can be recontoured, in some cases, through blasting and dozing to blend in with the surrounding relief.

Pit excavations can also be used for disposal of other surplus materials, but strict controls have to be applied to avoid ground-water contamination and gaseous emissions.

In cases where the pit is a shallow excavation of large lateral extent above the water table and not backfilled due

Fig. 2. Reclamation of terraced mine dumps. In the example of a dump that is not terraced, the net result is a threefold increase in material dozed and a threefold increase in dozing distance, leading to a total cost increase of nine times that of the terraced dumps.

to a lack of material, the pit can be reclaimed by spreading topsoil and planting suitable vegetation on the pit floor.

GROUND WATER AND CONTAMINATION

Economics dictate that the mine waste be disposed of in the proximity of the mine. This, in turn, limits the selection of disposal sites free from any water course and/or closeness to the ground-water sources. Mine waste disposal can be done economically and be environmentally safe if hydrologic factors are carefully considered. With larger and better material handling equipment, surface mining operations have increased in number and size in hard rock, uranium, coal, and in other minerals. Not all mine wastes are detrimental to the water resources; however, a potential for surface and ground-water pollution does exist due to some of the contaminants found in mine wastes. The parameters that play an important role in determining the extent of possible pollution and the relative effort needed to counter the effects are: (1) type of mine waste, (2) location of disposal site, (3) climatic conditions, (4) method of placement, (5) foundation condition, and (6) regulatory requirements.

In general, mine waste materials consist of overburden, soils, and rocks and may or may not contain minerals and/or contaminants. Metal mine wastes, and many nonmetal mine wastes, in general, exhibit low contamination potential. In order to make mine waste dump operations a success, in terms of economics, stability, and environmental acceptabil-

ity, each site must be evaluated on a case-by-case basis. An overall feasibility and planning study should include the potential of water contamination. The study does not have to be extensive, but must identify the constituents that may be regarded as potential sources of contamination. Based on a mineralogical study, the waste material may be grouped into low, moderate, or high potential categories.

Location of the dump site should also be taken into consideration, since a dump in an isolated area may require different consideration than one located in proximity to a populated area. Other location considerations are:

- 1) Dump placement in a stream, as a valley fill.
- 2) Dump placement on a mountain ridge or a side hill.
- 3) Upstream watershed.
- 4) Location of ground-water table and seasonal variation.
- 5) Type of downstream water utilization.

Climatic conditions also are an important factor in an environmental study. As an example, if certain minerals are detached due to frequent water action, the dump, which might have been regarded as noncontaminating in an arid climate, may become a major source of water pollution in an area that receives more precipitation. Also, weathering of the waste material would contribute toward physical contamination of the water, i.e., erodible material would transport as sediment in the surface runoff. This physical contamination is mainly restricted to surface water and can

be dealt with easily by providing peripheral diversion ditches and sediment collection ponds.

The design of sediment ponds and diversion ditches depends upon the site's specific conditions and upon regulatory requirements.

How the waste material is to be deposited would also influence the potential release of contaminants from the dump. Of particular importance from the water pollution standpoint is the permeability of the dump. A waste dump created by end dumping normally tends to be loose and more porous, exhibiting high permeability. On the other hand, a dump constructed in layers exhibits low permeability and has a lower rate of infiltration which, in turn, reduces the risk of contaminating water resources.

From the ground-water impact standpoint, important factors are the permeability characteristics of the soils and bedrock upon which the dump is constructed and the topography of the area. As an example, if the dump is placed on relatively level ground, ample time is provided for infiltration since a perched water level would be created within the dump, and this would allow the water to react with dump material. In contrast, a dump placed on steeply sloping ground under similar precipitation conditions would allow less time for infiltration.

The surface water and ground-water measures taken should, of course, comply with applicable regulatory requirements.

Surface Water

Physical and chemical contaminants can be treated easily through the use of a sedimentation pond. A pond constructed downstream of the dump will retain eroded material transported in the water and collected runoff then is released through an outlet mechanism. For chemical contaminants, it would be essential to determine the amount and type of chemical constituents prior to specifying the necessary treatment. Generally, metal mine wastes will not contaminate the surface water, and, therefore, treatment may not be necessary. However, it would be prudent to collect water samples and determine the water quality. To this end, it is recommended that surface water quality analyses be conducted prior to the commencement of mining activities. The design of sedimentation ponds and their appurtenant works should be based on prudent engineering practices and should meet the appropriate regulatory requirements. At present, the surface coal mining regulations for the United States require that the sedimentation yield be calculated using either the universal soil loss equation or $304.8 \text{ m}^3/\text{ha}$ ($0.1 \text{ acre-ft per acre}$) of disturbed area within the upstream drainage area.

Although the universal soil loss equation was developed to predict erosion from agricultural land, it is useful in estimating the sediment load from the disturbed area. Recent research activities have been directed toward estimating sediment load from surface mining activity. In addition to the estimation of sediment load, the following hydrologic criteria should be considered in designing a sedimentation pond as set forth in 30 CFR 816.45-.47 and .49 (Code of Federal Regulations, Title 30, Mineral Resources; current issue revised as of July 1, 1984, and reissued each July 1).

1) *Detention Time*—The sedimentation pond should have a capacity sufficient to provide a theoretical detention time of 24 hr for the 10-year, 24-hr precipitation event. It must provide adequate detention time to allow the effluent from the ponds to meet state and federal effluent limitations [30 CFR 816.46(c)(iii)(B)].

2) *Dewatering*—The storm storage should be evacuated through a nonclogging device such as a conduit spillway. The inlet elevation of the discharging mechanism should be at or higher in elevation than the maximum sedimentation storage volume.

3) *Emergency Spillway*—The emergency spillway in combination with the principal spillway must be capable of safely passing a 100-year, 6-hr precipitation event [30 CFR 816.46(c)(iii)(I)(2)(a)] or, if of smaller size as defined in § 77.216(a), must be capable of safely discharging a 25-year, 6-hr precipitation event [30 CFR 816.46(c)(iii)(I)(2)(c)].

Embankment Design

The design of the embankment should be performed in accordance with prudent geotechnical engineering principles and practice. Mine waste, if suitable, can be used in the construction of the embankment. The following criteria, as set forth in 30 CFR 816.49, should be met in the design of the embankment:

1) Embankments shall have a minimum static safety factor of 1.5 for the normal pool with steady seepage saturation conditions and a seismic safety factor of at least 1.2.

2) Embankments shall have adequate freeboard to resist overtopping by waves and by sudden increases in storage volume.

3) Foundation and abutments for the impounding structure shall be designed to be stable under all conditions of construction and operation of the impoundment. Sufficient foundation investigations and laboratory testing shall be performed in order to determine the design requirements for foundation stability.

4) All vegetative and organic materials shall be removed and foundations excavated and prepared to resist failure. Cutoff trenches shall be installed if necessary to ensure stability.

5) Slope protection shall be provided to protect against surface erosion at the site and protect against sudden draw-down.

6) Faces of embankments and surrounding areas shall be vegetated, except that faces where water is impounded may be ripped or otherwise stabilized in accordance with accepted design practices.

7) Impoundments shall include a combination of principal and emergency spillways which shall be designed and constructed to safely pass the design precipitation event (see previously).

8) The vertical portion of any remaining highwall shall be located far enough below the low-water line along the full extent of high wall to provide adequate safety and access for the proposed water users.

The design criteria for the sedimentation ponds (impoundments) described, although they appear to be stringent, are, in most cases, not overly difficult to incorporate. The design and construction of such facilities can be achieved economically and practically by including the system in the overall mine and waste dump planning efforts. It should be noted that these reflect current regulations and, as such, can change in the future.

Removal of Sediment, Maintenance, and Monitoring

Accumulated sediment should be removed from the pond when 60% of the design capacity is utilized. The removed sediment can be hauled to and deposited on the dump. The embankment and appurtenant works should be monitored and maintained so that the structures will continue to func-

tion as intended. The settling pond monitoring program should include:

- 1) Sediment level.
- 2) Water level and quality.
- 3) Seepage through embankment and foundation.
- 4) Sediment accumulation in outlet pipes.
- 5) Functioning of gates and other mechanical systems.
- 6) Observation of embankment for any signs of deterioration.

Ground-Water Contamination and Monitoring

Generally, metal and nonmetal mine waste will not contribute to the ground-water contamination. However, in surface coal mines the materials immediately above and below the coal are likely to contain pyritic shale which, in time, may impact on the ground water. In addition to the waste materials, climate, topography, geologic features, and the ground-water level below the ground surface can affect the levels of ground-water contamination. Careful planning and proper placement of materials can avoid the risk of contamination.

A ground-water monitoring program should be established to evaluate the impact on ground water. This program should include:

- 1) Installation of observation wells upstream, downstream, and in the vicinity of the waste dump.
- 2) Water level readings on a regular basis covering wet and dry seasons.
- 3) Water quality analysis by collecting water samples from the observation wells.

Results of water level fluctuations and water quality dated prior to construction of a waste dump and during the operation should be compared to determine the impact on ground-water contamination.

PERMITTING

Permitting for the disposal of mine waste can be considered an integral part of the permit requirements related to the mining operation, reclamation, operating plans and procedures, and water pollution measures. With the recent developments in regulatory requirements and procedures, it is common for many federal and state regulatory authorities to become involved. Federal acts and authorities that may be currently applicable but may change in the future are:

- 1) National Environmental Policy Act (NEPA) of 1969, NEPA 42, United States Code (USC) 4321, et seq.

- 2) Federal Water Pollution Control Act Amendments of 1972, amended as Clean Water Act of 1977 and further amended by Clean Water Act of 1978, 33 USC 1251 et seq.

- 3) Resource Conservation and Recovery Act (RCRA) of 1976, 42 USC 6901 et seq.

- 4) Federal Mine Safety and Health Act of 1977, 30 USC 951 et seq.

- 5) Surface Mining Control and Reclamation Act of 1977 (for coal), 30 USC 1201 et seq.

Timely commencement of the mining operation will contribute considerably in monetary gain and, therefore, it is essential to determine, file, and obtain approval for all the necessary regulatory permits. Overburden and leach dumps are subject to Environmental Protection Agency Regulations, 40 CFR 240 et. seq. Currently, however, specific requirements exist only for hazardous solid wastes. The Nov. 19, 1980, amendment excludes solid wastes from the regulations pertaining to the extraction, beneficiation, and processing of ores and minerals, except for coal, phosphate rock, and overburden removed for the mining of uranium ore. Most of the regulatory provisions of 30 CFR are directed toward mining, operational safety, and health controls; however, the Office of Surface Mining Regulations 30 CFR, Pt. 710 through 950, cover surface coal mining and surface activities for underground coal mining. Of particular importance for surface coal mining activities is Pt. 816 of 30 CFR.

Regulations, permit requirements, and permitting agencies often change, so it is recommended that in order to acquire an up-to-date detailed description of these requirements, the appropriate state and federal agencies be contacted at the outset of the mine planning program.

Listings of federal agencies and agencies involved in permitting and/or administering in selected western states are presented in Tables 1 and 2, respectively.

5.7 SURFACE COAL MINES

PHILIP G. MOREY

There are two different, but valid, approaches in surface mine design. One approach is to consider the problem to be defining the sequential removal of blocks of material to satisfy the criteria of production. However, an equally valid approach—and one shared with the majority of operations-oriented mining engineers—is that material movement is inextricably bound with the equipment used. To these engineers, mine design that does not specify the equipment and how it is employed is incomplete. In such an environment, the selection of equipment will affect the sequence and the dimensions of the material blocks to be moved, even as the material will affect the selection of equipment. The two considerations are two aspects of a single problem. This latter approach is the basis of the following discussion on surface coal mine design.

Surface coal mining generally involves removal of large amounts of overburden or waste for every ton of coal produced. Higher productivity per unit invested and per man-shift is achieved in surface coal mining than in underground coal mining. For example, underground productivity per man-shift varies from approximately 14 to 73 t (15 to 80 st), depending on the mining method. Surface coal mining productivity per man-shift generally ranges between 18 to 181 t (20 to 200 st), depending on the mining method and the amount of stripping required to uncover coal. At most surface coal mines, removal of overburden accounts for a high percentage of total mine investment and operating costs.

Because the working area is relatively unrestricted, compared to an underground working area, large excavating and haulage equipment can be used. Because such large equipment units are involved in the mining process, individual equipment units can be interdependent. For maximum productivity and efficiency, it is necessary to match equipment units to each other and to the ratio of materials that must be removed. In turn, the mine design must match mine equipment to geologic constraints of the deposit.

Selection of a mining system must be based on careful consideration of several factors, including geographic and geologic information, size of the deposit and the distribution of coal seams, availability of equipment and its compatibility with other equipment. The expected mine life, rate of production, and production buildup also must be given consideration in order to select a mining system that provides the most favorable engineering economics.

GEOGRAPHIC FACTORS

The geographic location of the surface coal mine may govern the adaptability of mining equipment. Periodic and annual rainfall, temperature extremes, unusual weather conditions, and altitude may affect equipment productivity and mine design. For example, surface mine design and equipment selection for an east Texas lignite mine must consider the impact of rainfall in the area. Wet overburden is difficult to handle, pit and waste slopes are difficult to maintain, pumping of water from the pit will be required, and haul roads must be specially constructed and maintained in order to be passable during inclement weather. In northern climates, extreme winter temperatures may affect the scheduled working days and equipment productivity. Frozen soil may have to be drilled and blasted before it can be excavated.

Equipment must be constructed with special materials to withstand temperature extremes. The impact of climate must be considered carefully before proceeding with the design and implementation of a mining plan.

GEOLOGIC FACTORS

Area topography and geology generally are the most important factors affecting the selection and design of a surface coal mining system. Surface attitude, number of minable coal seams and their general dip may limit the mining system alternatives.

Desired quality of the run-of-mine (ROM) coal produced may complicate mine design by increasing the number of production areas that must be made available. Thickness and characteristics of overburden and interburdens will influence system design and the selection of major and secondary excavation equipment.

The mine design engineer is not expected to be a knowledgeable coal geologist. However, it is important for the engineer to understand the analytical methods and tools used by the geologist so that geologic results can be utilized with confidence for mine design. During an exploration program, the experienced coal geologist collects data from which depositional environment and stratigraphy can be interpreted. Its accurate interpretation, coupled with good coal seam correlation, establishes the framework for mine design, environmental analysis, and feasibility studies.

The geologist uses his experience to identify basic lithology from the exploration drill-hole cuttings and cores. The information results in the identification or recognition of different materials in the stratigraphic column. Since most of this identification is made by the inspection of drill cuttings, the vertical position of strata is only approximate. A further problem exists in the identification of various coal layers within the stratigraphic column. Seams vary in dip and thickness, frequently part (divide), disappear, and reappear.

The coal geologist utilizes geophysical drill-hole logging techniques combined with cores and drill-hole cuttings to correctly interpret and locate lithologic sequences (Anon., 1981). These logging tools are:

Gamma ray reacts to the potassium isotope K40 that is present in most shales. The *shale line* is the estimate of where 100% shale would be represented on the log. Sandstones and sand typically have values much less than shale. The *sand line* is the estimate of 100% sand (0% shale). Readings between the sand line and shale line usually indicate sandstones and shale. Readings above the shale line generally indicate the presence of marine bands such as coal or uranium mineralization. Inferior coal may also give readings within the sand and shale lines.

Density log is a measurement of the bulk density of material through which the hole has been drilled. The density log of coal is unique because of coal's low density and may clearly distinguish between materials of near-equal gamma ray deflection. The *long-spaced density probe* permits deeper penetration of induced gamma rays into material, thus providing a better estimate of rock density, but decreased sensitivity to identifying contacts between beds of material of different density. The *bed resolution density probe* permits

accurate identification of bedding contacts with decreased accuracy of bulk density.

Caliper log measures variability in the diameter of the drill hole. The caliper log is used to compensate for density readings in caved areas of the hole.

Neutron log responds to hydrogen, and to a lesser extent, to carbon, and generally confirms the gamma ray log. Readings for coal are high because of the hydrogen and carbon content; shale readings are high because of the OH content present in mica and because of free water content in the shale. Sandstone and limestone differ due to variations in porosity and the effect of contained water.

Resistivity log responds to variation in electrical resistivity of material. Usually, shale readings are low and all other materials, including coal, are higher than shale. However, local variations can occur that will cause coal and sandstone to respond with low readings. Therefore, the resistivity log should be used primarily as a confirmation tool in conjunction with other logs. Exclusive reliance on the resistivity log can cause serious errors in seam correlation.

Sonic log gives a measure of compressibility and responds similarly to the density log. The sonic log can be utilized as a coal rank indicator, especially in defining inferior coal portions that may lay within a major coal seam. As with the resistivity log, the sonic log should be used more as a confirmation or ranking log.

The sonic log, in combination with the density log, can provide the basis for comparing relative strength, S , of material. The general formula is expressed as:

$$S = P/a - \Delta t^2$$

where P is the density of material, mass per unit volume; t is the sonic transit time per unit length; and a is a gravitational constant in appropriate units.

The gravitational constant, a , equals:

1.0	$\frac{\text{kg/m}}{\text{N/sec}^2}$	in International units
32.2	$\frac{\text{lbm/ft}}{\text{lbf/sec}^2}$	in English units

Gamma ray and neutron logs are especially useful in cased holes; the casing has no effect on their response.

Fig. 1 compares each log response to the drill-hole lithology. Based on these logs and identification of the materials, the geologist correlates various burdens and coal seams. From this correlation, considerable data can be compiled and presented in the form of geologic maps to assist the engineer in mine design.

In addition to the geophysical logs and drill cuttings, cores are taken from coal seams, including the seam contacts, for coal and ash quality analysis. Cores of overburden, interburden, and underburden also are taken for material strength analysis and environmental studies.

Each of the processes of data development serves a specific purpose. The potential accuracy of surface coal mine design is directly related to the quantity and quality of data developed. The geophysical logs, in particular, should be considered as a set of tools for data development. No single log should be used for correlation.

Fig. 2 illustrates a typical topographic map. Topographic maps, generally at a scale of 1 in = 100 ft (1:1200) or less, are preferred for detailed mine planning. Frequently, preliminary mine planning utilizes published US Geological Survey 7.5' quadrangles of scale 1:24,000. In the absence of suitable topo maps, aerial photographs or stadia surveys with ade-

Fig. 1. Geophysical logs as compared to drill-hole lithology.

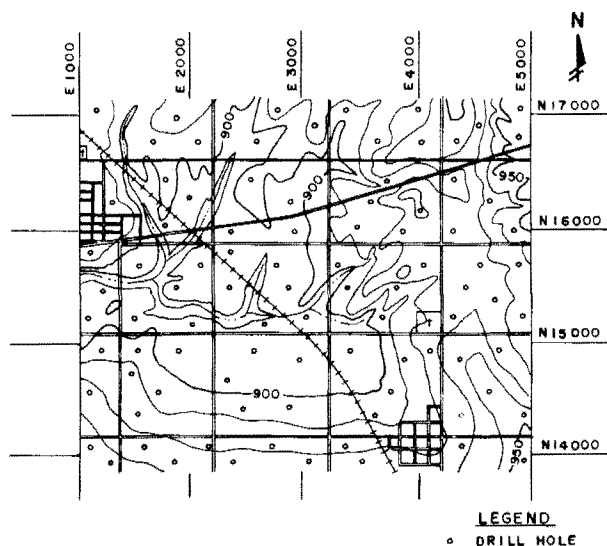

Fig. 2. Topographic map.

quate ground control may be used as a mapping base. Occasionally, topo maps—originally prepared from aerial photos—are in error. Topo maps provide information about surface features necessary for mine design. In addition to providing contours, regional drainage patterns can be identified. Any known environmental impact that may restrict mine design will be shown (townsites, isolated buildings, roads, trails, cemeteries, etc.). Generally, topo maps used during coal exploration become the base map from which the mine is designed. On these maps pertinent exploration data, such as drill-hole locations, are documented.

In addition to topo maps several geologic maps are essential for mine design:

Structure Contour Maps. Maps showing lines of equal elevation of a horizon of interest are known as structure contour maps. These maps are prepared to depict the structure of seams, and to show folds, faults, and other anomalies whose correct interpretation is critical for mine planning.

Isopachs. Maps indicating contour lines of equal thickness are known as isopachs. Overburden, interburden(s), and coal seam(s) isopachs contribute to understanding the three-dimensional geologic model of the coal deposit. Fig. 3 is an example of a coal seam isopach.

Isopleths. Maps indicating contour lines of equal value are known as isopleths. Ash, sulfur, moisture content, and coal heating value are commonly depicted on isopleths. Fig. 4 is an example of an ash content (percent) isopleth.

Resource Stripping Ratio Contours. Maps indicating contour lines of equal resource (vertical) stripping ratio contribute to understanding the economic or physical limitations of mining.

Stripping ratio is defined as the in-place volume unit of burden that must be removed to obtain one weight unit of recoverable coal as defined in cross section. To estimate recoverable coal, all inferior coal, top and bottom seam contacts, and partings must be removed from the total coal thickness measurements. When estimating the loss of coal at seam contacts, excavating or loading equipment that will make the separation at the contact must be considered. Also quality restraints may dictate the amount of coal that must be wasted at contacts. Generally, losses of 10 to 15 cm (4 to 6 in.) at top and bottom of each seam are allowed as equipment-generated losses.

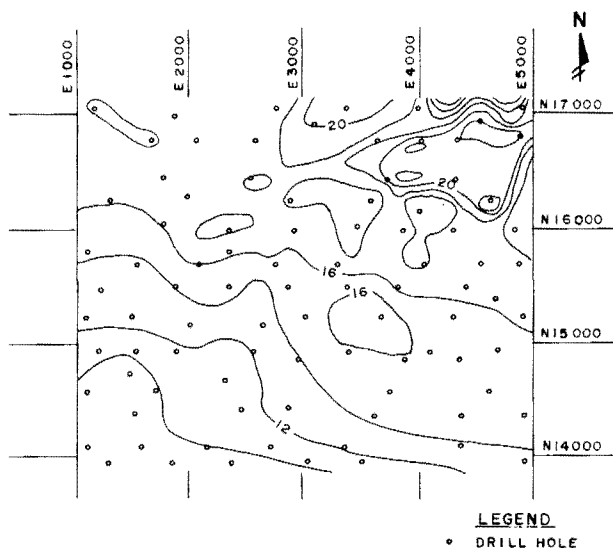

Fig. 3. Isopach of coal seam.

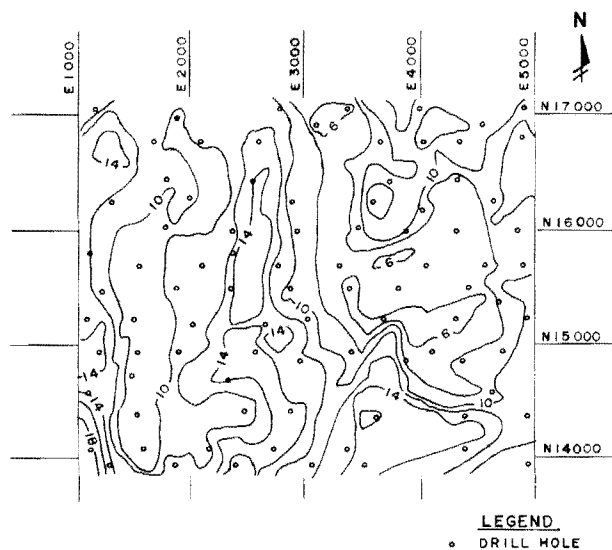

Fig. 4. Isopleth, percent ash.

The resource stripping ratio should not be construed as the true stripping ratio resulting from the mine plan. The resource stripping ratio is a first attempt to identify economically desirable deposit boundaries. The ratio does not include the impact of designed pit slopes and preproduction stripping.

All of these maps can be generated to scale by computer. Computer programs interpolate x , y , and z values from the geologic logs of bore holes to produce the desired map. It is most important to ensure that geologic logs are accurate, that computerized data is correct, and data processing performs correctly. Even though computerized data appears correct, inconsistencies in data gathering still may result in erroneous computer interpolation. To correct these errors, the geologist or engineer may be required to make judgmental corrections to ensure continuity of interpolation.

MINE DESIGN CRITERIA

Given the geologic data for a specific coal property, the next step is to define those factors that will influence or restrain mine design. In the initial planning stages of a new mine, the effect and interaction of these factors must be examined carefully in order to select the appropriate system among several available. Key parameters influencing mine design can be divided into three distinct groups: geologic, mechanical (equipment specifications), and operational parameters.

Geologic parameters dictate general pit features of depth, width, and slopes. Surface terrain, depth, and dip of coal seam(s) may limit mine design options. Geohydrologic and geotechnic parameters may restrict or eliminate equipment applicability. General geologic parameters governing mine design are overburden and interburden depth, thickness of coal seams and partings, density of burden and coal, burden swell factor, bench angles, and spoil angle of repose.

Mechanical parameters of equipment must meet the constraints of geologic parameters. Working radii of equipment units—dragline, backhoe, bucket wheel excavator (BWE) or shovel swing radius, truck-turning radius, scraper loading distance and turning radius—are related to the geologic parameters that impact the immediate working area.

Mine equipment design generally is based on standard specifications with limited flexibility. Therefore, physical lim-

itations are imposed on the immediate working area of an equipment unit. Mining shovel design limits the maximum controllable bench height while imposing minimum working bench widths.

Draglines impose similar limitations on working area geometry, but have somewhat more design flexibility. Dragline boom length and angle can be varied within specific limits. However, the maximum suspended load (bucket plus bucket load) will vary as boom length and angle are varied. The overall weight of the dragline impacts the safe working distance from the bench crest because of conditions of burden instability. For less consolidated burden, the dragline base, or tub, diameter can be increased to reduce the pound-per-square-inch ground pressure.

The first step in examining mechanical parameters is to determine the physical limitations that may restrain or restrict equipment operation. The second step is to assess the amount of flexibility for given mechanical parameters.

The general mechanical parameters are digging reach and depth, maximum load, ground pressure, equipment operating and clearance radii, dumping height, and work cycle time.

Operational parameters, in part, are dictated by the specifications of equipment capable of working under restraints imposed by the geology of the deposit. For example, the depth of burden is the major factor influencing the selection of a dragline. Because of the dragline's flexible mechanical parameters, several draglines and/or production rates may be considered. However, draglines are the most difficult to match to specific coal production rates. Varying depth of overburden and the options of varying panel width, digout length, boom length and angle, and bucket size must be examined jointly to estimate the most favorable mine design. In comparison, shovel excavators can be selected easily by designing more or less working benches with excavator units.

General operational parameters affecting mine design are scheduled annual working hours, operating efficiency factors, bucket fill factor, availability and utilization of equipment, mobility of equipment, downstream constraints on coal quality, and the desired coal production rate.

While the objective of general mine design is to develop a mine plan to produce a product at a desired and sustained level under the most favorable economic conditions, individual surface coal mine design frequently is affected more by matching geologic, mechanical, and operational parameters other than the desired production rate. Geologic parameters often limit the size of individual pit operations. Occasionally, geologic parameters dictate a greater, more favorable, production rate. For example, depth of overburden above a coal seam may require a very large dragline with sufficient digging depth and dumping reach to uncover the seam. Since burden removal is likely the greatest unit cost of this operation, the most favorable production rate will be the rate at which coal can be uncovered. To produce coal at a lesser rate would require the dragline to occasionally stand by to wait for coal production to catch up. Dragline standby would penalize overall economics of the operation.

DAGLINE STRIPPING METHODS

A simplified dragline operation is illustrated in Fig. 5. The stripping cycle begins with the dragline at position 1, cutting a trench, referred to as the *key cut*, along the newly formed highwall. The distance from the previous key cut position to the new position is referred to as the *digout* length. The key cut is made to maintain the panel width and uniform highwall. Without a key cut, the panel width would narrow with each subsequent digout, because the dragline could not

Fig. 5. Typical dragline operation.

control the bucket digging against an open face. The dragline deposits the key cut material in the bottom of the mined-out pit off the coal and against the previous spoil pile. More stable spoil from the key cut may be placed in the very bottom next to previous spoil to form the buckwall which provides a more stable spoil slope that can be steepened if deemed necessary.

When the key cut has been completed, the dragline is moved to position 2 to complete excavation of the digout. This is known as the *production cut*, and the material is cast on top of the key cut spoil. When the digout has been completed, the dragline is moved to position 3, the beginning of the next stripping cycle (next digout).

The operating cycle of the dragline consists of five basic steps:

1. The empty bucket is positioned, ready to be filled.
2. The bucket is dragged toward the dragline to fill it.
3. The filled bucket is simultaneously hoisted and swung over to the spoil pile. If the swing motion must be slowed to permit hoisting, the dragline is said to be *hoist critical*. When hoisting to the dump position is completed before the boom is in position to dump, the dragline is said to be *swing critical*.
4. The material is dumped on the spoil.
5. The bucket is swung back to the cut while simultaneously being lowered and retrieved to the digging position.

Efficient dragline operation is realized by minimizing the time required to position, drag, and dump while synchronizing the swing and hoisting motions. Synchronization of hoisting and swinging is dependent on the time the boom is in motion.

Full Key Cut vs. Layer Cut

At the beginning of a new digout, the dragline generally is placed directly over the toe of the new highwall to be formed. From this position, the dragline can establish a uniform and safe highwall if the burden is sufficiently stable.

In this position, the dragline excavates the key cut which is more than the width of the bucket at the bottom of the cut. When the cut has been completed, the dragline moves over to make the production cut. The two positions generally are required because of the limited reach of the dragline in relation to the panel width being stripped. Large draglines, operating under ideal conditions, may be able to excavate the total digout from the one position over the highwall. Such situations are the exception, not the rule.

When operating conditions permit excavation of the digout from one position over the highwall, the dragline generally excavates the digout in layers. The key cut is formed, one layer at a time, by excavating along the highwall before the completion of each layer. Cutting in layers can be performed from the production cut position; however, the highwall slope will require dressing by dozer while the dragline is digging. Under such circumstances, some mines also have adequately dressed the highwall by dangling a heavy section of chain from the bucket and dragging the chain along the wall. Other mines, because spoil area is critical, have progressively stepped the dragline toward the spoil while excavating in the layer cut method. This procedure has the tendency to pack spoil as tightly as possible on the spoil slope.

Layer cutting generally increases dragline productivity with a corresponding decrease in operating cost. Increased productivity is realized by progressively decreasing the average swing angle as the dragline walks in the direction of the spoil pile.

Dragline Panel Width: Panel width is defined as the width of the cut taken by the dragline, as it progresses from digout to digout, along the highwall from one end of the pit to the other. Panel width, one of the most important parameters affecting dragline productivity, is influenced by depth of overburden, dragline boom length, hoist and swing time, and available spoil area. Since panel width becomes the available operating area in the pit bottom, coal loading operations are also affected.

Several operational factors must be considered in the selection of panel width. A wide pit generally is favorable for coal loadout and permits greater safety for men and equipment. The minimum practical pit width is dictated by the maneuverability of coal loading and hauling equipment.

If the available space for placement of spoil is critical, such as might occur when crowding spoil to open haul roads through the spoil, narrow panels permit greater flexibility to deal with such problems. In general, the wider the panel, the less dragline walking time is required.

Productivity variations, because of panel width, are directly related to whether or not the dragline is swing critical. Small draglines can become swing critical at panel widths less than the width required for practical coal operations in the pit. Their cycle time also increases dramatically. Larger draglines may not become swing critical until the panel width exceeds 50 m (150 ft). Fig. 6 compares cycle time and productivity vs. panel width for large and small draglines.

Bench Height: The height above the coal seam at which the dragline is positioned is defined as the bench height. Selection of the bench height is based on numerous operational factors and topographic restraints.

The complex relationship of bench height (which could be equal to overburden depth), panel width, dragline dumping reach and dumping height, as well as material characteristics such as swell and angle of repose, influence greatly the dragline's capability to dispose of burden off the coal.

Fig. 6. Cycle time and productivity vs. panel width for large and small draglines (Anon., 1978).

The dragline's digging depth, while related to burden depth, rarely becomes a factor in dragline performance.

The bench height must be selected primarily on the basis of fitting the dragline's specific characteristics to the required pit geometry. In general, the bench height should be as high as possible within the limit of required dragline reach.

Undulating topography may complicate a simplified selection of bench height. Two alternatives are available to alleviate the problem:

- 1) The dragline can be used to cut and fill to develop a common bench elevation. Cutting, termed *chopping* or *over-hand digging*, increases the cycle time and reduces the bucket fill factor, thereby reducing effective productivity. Fill material must be rehandled, thus reducing overall production. Chopping has very special advantages: the dragline reach required may be shortened, rehandling of burden may be avoided, fill may not be required to create a level working surface, a level return path for deadheading can be provided, and subsoil can be placed back in its relative position on top of the spoil.

- 2) Auxiliary equipment can be used to perform the cut and fill operation. Care must be exercised to ensure that filled areas are stable. Utilizing auxiliary equipment offers the benefit of freeing the dragline for its primary function of stripping burden from the coal.

Whether the dragline cuts and fills its working pad or auxiliary equipment is utilized to prepare a level working

surface depending on several variables. Dragline chopping decreases overburden stripping productivity and may involve abnormal wear and tear on dragline equipment. Auxiliary equipment for prestripping adds to the capital and operating costs of operations. Depending on the thickness of the material to be chopped, the cost differential between chopping and using auxiliary equipment is not likely to be high when small draglines are compared. For large draglines, prestripping with auxiliary equipment will very likely be preferable.

Digout Length: The selection of digout length, the length between major digging cycles, is based on the relationship of the dragline's operating characteristics with respect to pit geometry. In general, the digout should be as long as possible. However, dragline size may greatly influence digout length for specific pit geometry. For example, digout length is sensitive when using a dragline with slow hoist speed working in deep overburden. Spoil critical pits may utilize a less than desirable digout length in order to pack the maximum material onto the spoil bank.

In general, a long digout with respect to dragline size reduces cycle time and increases productivity because more material is loaded under the outer end of the boom than near the fairleads of the dragline. A good dragline operator will try to fill the bucket within two and a half to three times the bucket length. Cycle components of retrieving for bucket loading, bucket dragging, payout for dumping, and swing angle all are decreased as the digout length increases. Longer digout lengths also reduce the nonproductive time required for repositioning the dragline on the succeeding digout. Obviously, digout length should not be so long as to require the dragline operator to cast the bucket beyond the limit of the boom.

Walking Patterns: In a dragline operation, two separate walking cycles are involved: *deadheading* and *walking within the digout* (see Fig. 5, positions 1, 2, and 3). When a panel has been completed, there are two options available for the dragline. One, the dragline can wait for the coal to be mined to the end of the pit, then turn around and begin the next panel in the opposite direction. This procedure is termed *laying over* at the end of a panel. Two, the dragline can turn around and travel part or all of the way down the panel to begin the next cut. This procedure is termed *deadheading*. If the dragline travels part way down the panel, it cuts into the next panel and strips in the opposite direction. If the dragline travels to the other end of the pit, it cuts in to the next panel and strips in the same direction.

Whether a dragline lays over or deadheads depends primarily on the production time lost. Contractual requirements, such as exposed coal inventory, may eliminate the layover option and force deadheading. Some mines opt to lay over at the end of a panel because ground conditions are not favorable for deadheading. Other mines limit layover to a maximum of two shifts. If waiting for coal production involves two or more lost dragline shifts, the dragline will be deadheaded.

When deadheading is feasible, the decision should be made on the basis of minimum lost dragline production. Fig. 7 illustrates the approximate time required for deadheading draglines. Deadhead time is based on 33% of the specified dragline walking speed. Such a large discount factor must be used to account for various delays in deadheading, such as maneuvering, cable handling, ground preparation, and minor breakdowns.

In Fig. 5, the standard dragline positions within the digout were illustrated. From position No. 1, the key cut is

Fig. 7. Deadhead time vs. distance (Anon., 1978).

excavated; from position No. 2, the production cut. Realistically, additional positions are utilized by the dragline as layers are stripped from the digout. Depending on the location of the fairleads, it may be necessary to walk the dragline to successive positions systematically closer to the digout face to permit clearance of the bucket chains from the fairleads.

The greater the digout length, the less walking time will be required per panel. Repositioning in the digout can affect cycle time. Therefore, walking patterns must be considered when selecting digout length. Time spent in repositioning the dragline can be estimated by discounting the walking speed of the dragline. Generally the discount factor is much less than the factor utilized for deadhead estimates. Based on observations by the author, a discount to 15 to 20% is appropriate.

Pit Shape: The new dragline pit begins with the initial cut, termed the *box cut*, made along the outcrop, subcrop, or property boundary. To open the box cut, excavated material is spoiled to one or both sides of the cut. The material lying on the newly created highwall must be moved or spread out evenly by auxiliary equipment. The material lying on the cut wall that will become the spoil side may, or may not, have to be moved depending on reclamation requirements.

Because of rolling topography, the mine engineer may be inclined to design the box cut along a uniform contour. Generally, succeeding cuts are designed parallel to the box cut. As a result, this type of pit develops a meandering design. In Fig. 8, the effects of pit curvature are illustrated. The figure is an idealized compound curve with equal radii of curvature to illustrate the difference in spoil area between an inside and outside curve. Obviously, outside curves provide more spoil area. Depending on depth of overburden, panel width, radius of curvature, and operating parameters, severe operating problems may occur on inside curves. Dragline cycle time will increase, spoil crowding will occur, and coal may be lost by being covered with spoil.

To remedy the problems caused by inside curves, several options can be considered. Panel width may be decreased, material may be cast short and rehandled by extending the bench, a small auxiliary dragline may be utilized on the spoil to pull back excess spoil, the spoil pile may be steepened, or the pit may be straightened by stripping a series of short panels. Generally, the most favorable solution is to straighten

Fig. 8. Pit curvature.

the pit. Spoil steepening is also an effective method for disposing of relatively small amounts of excess spoil. The dragline bucket is positioned on the spoil slope where steepening is desired and dragged down and across the top of coal. The bottom part of the spoil pile is steepened and coal is cleaned in the process. Digging efficiency during this process is reduced, cycle time increased, and rehandling reduces effective productivity. Steepened spoil slopes may present special hazards to equipment and personnel because they are more prone to failure.

Spoil Patterns: There are three basic methods of spoiling. When using short digouts and casting at a near 90° angle, a uniform ridge line can be created. This configuration makes maximum use of the available spoil room. As the digout length is increased, uniformity of the ridge line is lost and individual peaks of spoil are created.

With sufficient spoiling area, the dragline operator may cast material from both the key cut and production positions at angles less than 90°. While the dragline stripping cycle will improve, spoil piles appear to be ragged and irregular. An aerial view of the operation will show a definitive pattern to the irregularity. In reality, spoil peak grading will be reduced by this method of spoiling.

Dragline cycle time can be reduced by dumping the loaded bucket on the fly, that is, before the dragline swings to the ultimate dumping position. This procedure, termed *radial casting*, gives the spoil a cross bedded appearance. Provided that there is sufficient spoil room, radial casting tends to spread the spoil more effectively, reducing spoil grading costs.

Since distance between spoil ridges is equivalent to the panel width, narrower panels will reduce spoil grading costs. However, such reductions in cost generally will be offset by increases in dragline operating cost if the dragline is not swing critical.

Dragline Extended Bench Systems

Where overburden depth or the panel width exceeds the limit at which the dragline can sidecast the burden from the coal, a bridge of burden can be formed between the bank and the spoil which effectively extends the reach of the dragline. The bridge extends the bench on which the dragline is operating. The bridge is formed by material falling down the spoil bank or by direct placement with the dragline. To remove the bridge material from the top of coal, it must be rehandled.

Extended bench systems are adaptable to many configurations of pit geometry. Fig. 9 demonstrates a dragline forming its working bench by chopping material from above

Fig. 9. Extended bench and crop cut single dragline.

the bench and forming the bridge, then moving onto the bridge to remove it from top of coal.

Fig. 10 demonstrates a two-dragline extended bench stripping sequence. The primary dragline strips overburden and spoils it into the previously excavated panel. This material is leveled, either by tractor-dozers or the secondary dragline, to form the bench for the secondary dragline. The secondary dragline first strips material near the highwall, then moves on to the bridge to move the rehandle material. In a two-dragline system, one machine must operate at the pace set by the other. Therefore, mine design must consider their respective capacities when assigning respective digging depths.

Fig. 11 illustrates an extended bench operation in which three coal seams are to be recovered. The primary dragline strips overburden to the top of the first seam. Coal is removed, then a small parting dozed into the pit and the second coal seam removed. The secondary dragline strips the large interburden to the third and final seam.

Fig. 10. Two dragline extended bench system.

Extended bench systems must be designed carefully in order to maximize the dragline(s) productivity and to minimize the amount of rehandle.

Contour Stripping with Draglines

In this method, dragline stripping proceeds along the coal outcrop or subcrop, with each successive panel following the line of the original panel. In rolling terrain, the pit twists and turns, developing a series of *S* curves. If the dragline is operating at near maximum geometric limits, it will become *spoil-bound* (unable to deposit stripped burden) when working an inside curve. Under such conditions a smaller secondary dragline may be used to pull back the spoil sufficiently to permit the primary dragline to complete stripping of the coal. Haul roads generally are designed into an outside curve where some spoil crowding is possible because of the wider spoil bank arc.

Dragline Pull-Back Method

Occasionally, overburden to be stripped will be beyond the capacity of the dragline to spoil off the coal by any of the previous methods described. In this case, a secondary dragline can be placed on the spoil bank to pull back sufficient spoil to make room for complete removal of overburden.

The pull-back method is illustrated in Fig. 12 in which a small dragline is pulling back overburden at inside curves of a contour mine.

Generally, rehandle volume is greater for the pull-back than an extended bench method of operation. However, where used as illustrated in Fig. 12, it may also serve to level spoil piles in addition to providing more spoil area for the primary dragline.

If the overburden/interburden is generally beyond the capability of draglines working on the highwall, the pull-back method would seem to be a solution. However, great care must be given to the design of this method because of the inherent hazards of operations. Spoil slopes can be unstable, more so during periods of severe rainfall.

Draglines frequently are utilized to strip overburden from deeper coal seams than originally intended. Occasionally, spoil slopes cannot be maintained at designed angles. Various methods have evolved to stack more material into the spoil bank to alleviate these problems. The more common methods are described briefly:

Buckwalls involve building the base of the spoil adjacent to the pit with competent material so that a steeper spoil slope near the base can be maintained.

Coal fenders require leaving a small wedge of coal untouched in the pit so that more spoil can be packed on the spoil slope.

Outside pit involves modifying the pit shape in order to develop the outside curve concept which increases the spoil area relative to the stripping area.

Fig. 13 demonstrates a modified outside curved pit plan developed at a southern Illinois mine. This plan permits stacking of extra spoil on each side of the designated pit haul roads and also dramatically decreases the time required to

Fig. 11. Two dragline extended bench for three coal seams.

deadhead the dragline from one panel to the beginning of the next panel. This plan will work well if doglegs are maintained at 60°. Lesser angles will work if overburden is shallow and the dragline is oversized in relation to its digging depth.

Drilling and Blasting of Overburden for Draglines

Overburden drilling and blasting is more critical for dragline stripping than for shovel digging. Shovels have the ability to crowd the dipper into the bank, providing leverage to dig difficult or poorly blasted material. Draglines have leverage only by dragging the bucket over the material. Such leverage is translated to severe strain on the bucket lip and teeth. In poorly blasted material, dragline productivity can drop more rapidly than that of shovels working in similar material.

Selective placement of explosives and blasting agents may be critical to the surface coal mine operation. Many coal seams are overlain with sedimentary beds of varying hardness and thickness. Improper placement of the charge in the blast-

Fig. 13. Modified outside curving dragline pit.

hole can cause blast energy to travel along planes of greater weakness and through softer material. Under such conditions, harder beds of material will tend to break in large blocks or fragments. To ensure adequate placement of the blast charge, it is necessary that drill operators log differences in material or drill penetration rates and provide this information to the blasting foreman.

For dragline stripping, there are two general methods of blasting overburden in common use. One method utilizes a blasthole pattern with a buffer zone to contain the blasted material against the highwall. Fig. 14 illustrates this pattern. The advantage of this pattern is to contain the blasted material within the dragline working area and avoid large broken material that must be handled with difficulty.

The width of the buffer zone, combined with the powder factor, are critical elements in efficient utilization of this method. This method is useful, especially if the dragline is performing a chop cut prior to the key and production cuts.

The other method of blasting overburden is similar to the standard open pit blasting procedure. Its purpose is to blast as much material into the spoil area as possible, thereby reducing the amount that must be stripped by the dragline. The resultant advantage is debatable in the author's opinion,

Fig. 14. Blasting pattern to provide maximum fragmentation with a buffer zone (Anon., 1981).

since considerable grading is necessary before the dragline can begin casting. Frequently the dragline is called upon to rebuild its working pad by retrieving material from the pit. Time lost in pad preparation may completely offset the original reduction in stripping volume. If the dragline can safely work on the spoil side of the pit, building its working pad ahead on the spoil, there may be justification for blasting material from highwall to the spoil. Increased costs of explosives, pad building costs, and highwall scaling delays must be weighed against the difference in overburden volume to be stripped. Fig. 15 illustrates this blasting method with the dragline working from the highwall side.

Drilling and blasting techniques are covered more thoroughly in Chapter 6.

SHOVEL-TRUCK SYSTEMS

There are a multiplicity of geologic situations adaptable to a shovel-haul truck system for removing burden from coal. The shovel-truck system could be substituted for all of the foregoing systems. Generally, the shovel-truck system is considered for one of the following reasons:

- 1) The coal is sufficiently covered by burden to be beyond the digging depth of draglines.
- 2) The burden is sufficiently unstable that dragline operations would be hazardous.
- 3) Toxic material within the burden requires special emplacement in the spoil.
- 4) The coal seam is thick enough to prevent adequate dragline spoiling off the coal.
- 5) The burden must be drilled and blasted. When blasted, the broken material is blocky and does not swell sufficiently to facilitate easy digging. (Since shovel/truck removal of overburden generally costs three times as much as dragline stripping, or more, the costs of closer drill-hole spacing and increased powder factor for the dragline system should be examined as a possible alternative.)

Because of a wide range of equipment sizes, shovel-truck systems have a decided advantage when attempting to match specific production goals. The equipment fleet easily can be increased in proportion to increased coal demand.

The design of shovel-truck systems for overburden removal follows similar standards of operation as in general open pit design as described in Section 6.3. Perhaps the only significant difference is in the treatment of economic limits. In surface metal mines, variability of ore grade and current market price greatly influence the stripping ratio. In surface coal mining, however, the coal product generally has consistent quality over large areas. Therefore, stripping ratio and stable long-term market price contracts more directly control minable limits.

Stripping Shovel System

Stripping shovels fitted with long booms and long dipper sticks remove overburden from coal while sitting on the top

Fig. 15. Blasting burden into pit. (Note small area of muck requiring no dragline handling.)

of coal. Stripping shovels up to 138 m³ (180 cu yd) have been used for overburden removal in the midwest. Interest in stripping shovels has waned in the past decade because of their limited operating depth and relatively higher operating cost than the newer, longer boom, draglines. Where currently in use, stripping shovels are limited to relatively flat-lying seams and shallow burden. Because of their large crawlers, it is difficult to change their working bench level to follow undulating or pitching coal seams. As burden depths have increased, the mine engineer has been required to utilize auxiliary stripping equipment to remove near surface material in order to keep the stripping shovel working.

The pit configuration for a stripping shovel is similar to the basic dragline pit. The major parameters controlling its operation are the operating and dumping radii and dumping height.

The new, larger draglines with long boom and large bucket capacity have tended to render the stripping shovel obsolete.

Scraper Load/Haul System

Under favorable conditions, scrapers can be used for stripping overburden from coal. A scraper fleet, with appropriate support equipment, can offer many advantages over dragline or shovel-truck stripping systems. Rehandle of material is significantly reduced, spoil is more favorably placed for reclamation of the mined area, pit width can vary without materially affecting operations efficiency, safety is greatly improved, and traffic congestion in the coal loading area can be reduced. Fig. 16 is an illustration of a scraper load/haul stripping system.

The major parameters affecting design of a scraper load/haul system are pit depth, scraper loading distance, turning radius, hauling distance, rolling resistance, rated capacity, and permissible grade.

There are four basic types of scrapers with their selection generally being based on loading and hauling conditions and material characteristics. The conventional *single-engine scraper*, because it is push-loaded by a crawler tractor, can handle a wide range of material, job conditions, and haul distances. The *elevating scraper* self-loads with a powered

Fig. 16. Scraper haul mining system.

elevator that lifts material from the cutting edge up into the scraper bowl. It is limited to handling material up to gravel size because of the mechanical reliability of the elevator. The *dual-engine scraper* can handle the same materials as a conventional machine and is able to work in wet ground conditions where a conventional scraper might be limited by poor traction. *Push-pull scrapers* are dual-engine scrapers that work in tandem as a unit, the lead scraper first being push-loaded by the second scraper, then the second scraper being pull-loaded by the first. Once loaded, they separate and haul as individual dual-engine scrapers. Push-pull scrapers eliminate the need for push-dozers and generally can work in soft burden. For all four scraper types, very wet ground conditions reduce their productivity in varying amounts.

Various studies comparing scrapers to draglines have been performed by the author and others (Chironis, 1981; Anon., 1978). These studies have shown that scrapers should be considered in the removal of soft overburden less than 20 m (66 ft) in depth. While operating costs may be higher for the scraper system, initial capital investment is lower, thus creating a more favorable return.

Important in comparing the scraper system to other systems is the elimination of spoil grading equipment. Also, the self-loading scraper is frequently used for removing, stockpiling, and replacement of topsoil. Mine design utilizing a scraper haul system could eliminate the stockpiling phase of the topsoil removal and replacement cycle.

Most surface coal mines utilize scrapers for numerous reclamation activities. Some dragline operations put them to additional use for skimming off overburden in rolling terrain.

BUCKET WHEEL EXCAVATOR SYSTEMS

Given suitable geologic conditions, the bucket wheel excavator (BWE) can compete with dragline and shovel/truck systems. The BWE, a continuous mining system with high productivity, can be used as a primary or secondary excavator and is adaptable to all hauling and materials handling systems.

BWEs vary in size from an approximate theoretical output of 200 to 20 000 m³/h (262 to 706,300 cu yd per hr). The larger BWEs have been used extensively in German and Australian brown coals. The smaller BWEs have found wide acceptance in many East European countries, but only sporadically in the US and other parts of the world where their size is proportionate to material thickness or production requirements.

The BWE generally is limited to excavating material having a cutting resistance less than 70 kg/cm (4700 lb per ft). Table 1 lists specific resistances for various types of overburden and coal. Laboratory methods for measuring cutting resistance are indicative at best because theoretical measurements vary with the size of the sample tested. Therefore, they should be used only as a guideline for specific material.

The methods of BWE operation are described according to the position of the BWE when excavating the face: *frontal* or *face mining*, *full block mining*, and *half block mining*. In each method, there are two alternative cutting techniques: horizontal, termed *terrace cutting*, and vertical, termed *drop cutting*. Each operational method and cutting technique has specific uses and affects mine design differently.

The frontal or face mining method is especially useful in separating soil or sublayers requiring special placement in the backfill. In this method, the BWE moves along the face using either the terrace or drop-cut technique of slicing. For handling soil or sublayers, terrace cutting is preferable. The face mining method does not require a slewable boom, but

Table 1. Specific Cutting Forces of Virgin Material for Bucket Wheel Excavator Excavation

Material Type	Specific Cutting Forces, kg/cm
Earth	10–30
Loess	20–40
Sand (fine, coarse, wet, or dry)	10–40
Clayey sand	10–50

does require a long boom crowd. Face mining may be desirable if stable bench slopes can be maintained and if material is cast directly to the spoil side of the pit. Fig. 17 illustrates face mining with direct overcast.

Full block mining is the most common method utilized for removal of large, thick deposits of loosely to semiconsolidated material. The BWE continuously slews across the face block while the boom is crowded into the face. Terrace cutting the block is more common than drop cutting. If the boom cannot be extended (crowded), the depth of the terrace cut will be limited by the distance the BWE can advance. Use of crowdless machines must take into consideration the soil-bearing characteristics over which the machines must travel. Also, their crawlers are subjected to more mechanical wear and tear. Full block mining with shiftable bench conveyor is illustrated in Fig. 18.

Face block mining is particularly useful when it is desirable to remove extensive layers of overburden by terracing. The BWE, traveling parallel to the face, continuously slews across the face block in making the terrace cut. This method requires machines with long bucket wheel booms. Face block mining is especially useful in the selective excavation of topsoil or toxic layers requiring preferential placement. Fig. 19 illustrates the face block mining method.

Material removed by a BWE is overcast directly onto the spoil pile, transferred to large haul units, or to belt conveyors that transport material around the pit to the spoil.

A typical BWE mining system utilizing conveyors to transfer material to the spoil side of the pit will consist of

Fig. 17. BWE face mining with direct overcast.

Fig. 18. BWE full block mining technique.

Fig. 19. BWE face block mining technique.

several equipment units that comprise the system. These units may consist of:

BWE excavates in situ material and discharges it either directly into the traveling hopper on the face conveyor or into the load hopper of a band wagon or belt wagon.

Band wagon or *MTC* (mobile transfer conveyor) receives material from a BWE and discharges it into the traveling hopper on the face conveyor. Its primary function is to add horizontal and vertical range to the digging capabilities of the BWE, thus limiting the frequency of face conveyor moves.

Belt wagon is similar to a band wagon, but has a longer discharge boom and is also used as a stacker.

Conveyors

Face conveyor, located on an excavation bench parallel to the advancing bench face, extends the full length of the face and is equipped with a traveling hopper car that allows the conveyor to be loaded at any point along its length.

Side conveyor, located on the pit side at right angles to the face conveyor, receives overburden material from the face conveyor and discharges it onto the spoil conveyor.

Spoil conveyor, located on a backfill bench, receives overburden material from the side conveyor and discharges it into the load hopper of the belt stacker. This conveyor extends the full length of the backfill bench and is equipped with a traveling tripper car that allows the conveyed material to be discharged at any point along its length.

Belt stacker receives overburden material from the spoil conveyor and stacks it onto a backfill bench.

Ancillary equipment includes tractor dozers for bench preparation, leveling and spreading, and conveyor shifting.

As mining progresses, the BWE mining system must be moved. Because of lost production when shifting the conveyor components, mines incorporating BWE systems favor long mining panels. In addition to increasing output of the BWE, rehandle volume relative to the total deposit is reduced. Long panels, however, may not be the desirable mine design. Increased capital costs of conveyors and development of the box cut may offset the benefits of long mine panels.

Productivity of BWEs

Manufacturers generally quote BWE production in theoretical output. The theoretical rate must be discounted to account for lost productive hours due to equipment and system unavailability, lost time for nonproductive maneuvers, cleanup, etc., and operator inefficiency. Fig. 20 illustrates a typical distribution of hour components from which utilization, availability, and productivity are calculated. It is important to note in Fig. 20 that equipment operating costs are based on operating hours and productivity is based on effective productive hours.

As shown in Fig. 20, operating delays can represent a large percentage of scheduled hours. Therefore, care should be given in their estimation to ensure reasonable production estimates. Equipment rearrangement involves movement of BWEs from bench to bench in the pit. Face, side, and spoil conveyors must be moved after completion of each panel cut. Encountering large rocks will slow production while the BWE digs around and dislodges them. Adverse digging conditions may be encountered as in unstable face slopes. Digging conditions may require frequent stoppages for bucket cleaning. For example, in Australian brown coal mines, bucket plugging is so severe that Australian engineers have spent considerable effort in designing buckets that tend to be self-cleaning. This is accomplished by installing a loosely fitted chain matting in the cutout back of the bucket.

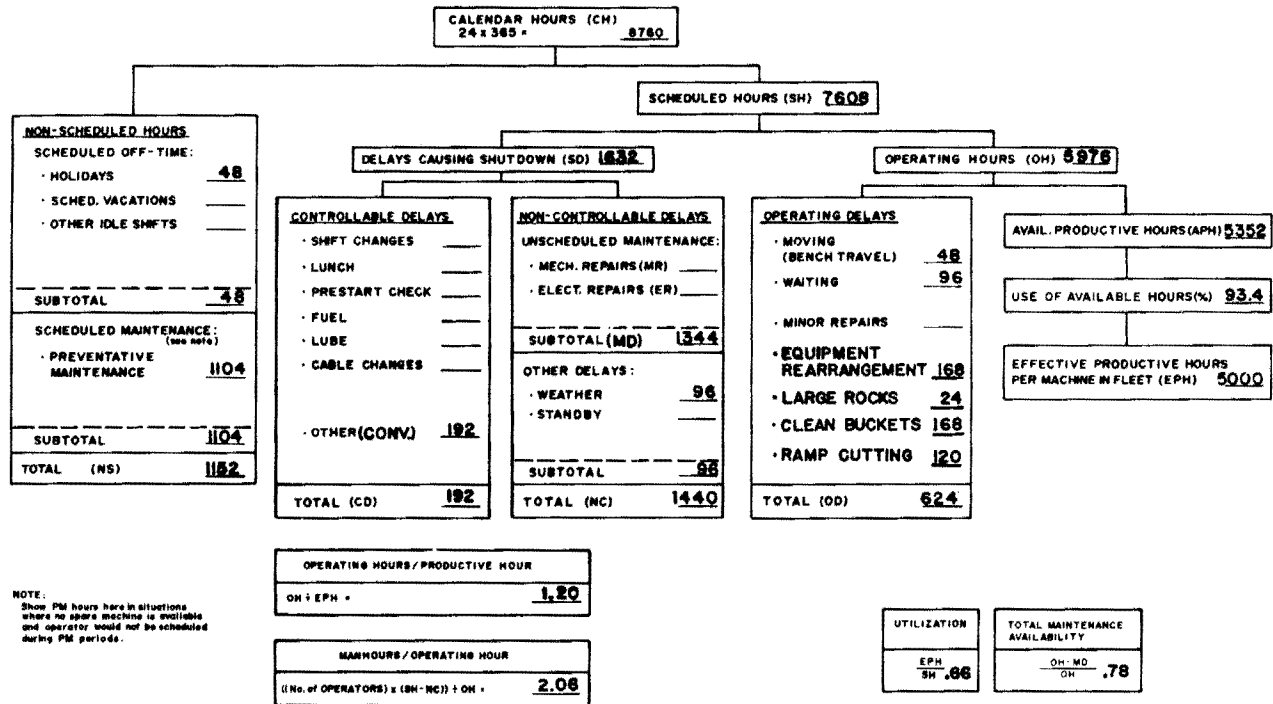

Fig. 20. Annual schedule of equipment hours for bucket wheel excavator.

Conveyor shifting is a time-consuming operation. To ensure rapid repositioning and realignment, conveyor shifting must be well coordinated. Shifting is accomplished by dozers fitted with a special clamp that grabs the rail of the conveyor base. At a travel rate of 5 km/h (3 mph), the belt can be shifted approximately 80 cm (31 in.) per dozer pass. When repositioning is complete, from one to three alignment passes are made with the dozer traveling at about 2 km/h (1.2 mph). Preshifting and setup preparation generally consume about 2 hr each. This schedule assumes well maintained working areas, equipment, and a well-coordinated shifting crew. Generally, the BWE and associated equipment undergo preventative maintenance while the conveyors are being shifted.

To compare a mine design consisting of several small or compact BWE systems with other primary excavators, consideration must be given to phased buildup of production, and under certain conditions, phasing in BWE systems may show more favorable economics than other primary excavators. On the other hand, large unit production requirements may dictate a BWE of such size that economy in scale may be offset by interest payments on capital investment.

Given appropriate digging conditions, the BWE should be given consideration in mine design because of its high production capacity and materials handling capabilities. Since the BWE is a highly specialized excavator, the engineer is referred to Anon. (1973) and Rasper (1975).

COAL REMOVAL METHODS

Conditions encountered in coal removal vary as much as in overburden removal. Coal removal must be matched to overburden removal in order to maintain a properly balanced production cycle. Since the stripping cycle generally is more cost sensitive than the coal loading and hauling cycle, coal loaders and coal haul fleets generally are oversized to actual

production requirements to ensure sufficient capacity to recover coal production lost by nonrelated stripping delays.

Coal loading from seams in narrow pits requires loaders with large operating reach and/or dumping height. Loading in narrow pits generally begins with the haul truck located on the top of coal and the loader in the pit bottom. The loading sequence ends with both units on the pit bottom. Fig. 21 illustrates a shovel with extended boom loading trucks in this manner. In unusual cases of bad pit bottom conditions, all coal removal may take place from the top of coal.

For normal loading operations, the engineer has the option of cable or hydraulic shovels or front end loaders. When pit bottom conditions are unsuitable, backhoes may be used for loading from top of coal. Scrapers also may be used for loading and hauling. In recent years, a new type of coal loading machine has been tested and, under specific conditions, has been found to perform satisfactorily. This loader, *Easi-Miner*®, consists of a tractor-driven rotating drum with ripper teeth offset on its circumference. The drum, hydraulically operated, rotates and chews up coal from top downward as the unit is slowly propelled forward. The unit can be controlled to very selectively mine layers of seam (or partings) from about 10 cm (4 in.) up to 60 cm (2 ft). While still considered to be somewhat a prototype machine, its workability appears very promising, especially in coals where production quality is demanding.

Fig. 21. Coal loading sequence in narrow pits.

Parameters affecting the coal loading elements of mine design are similar to those affecting overburden removal. Thickness and stability of coal seams, presence of removable partings, and stability of bench or pit bottom must be considered when making equipment selections. Selected equipment will have specific mechanical parameters such as operating radius and dumping height. Operating parameters such as production rate and equipment productivity will

affect equipment selection and pit design. Generally, several iterations of analysis of selected mechanical and operational parameters are required in order to develop a mine design compatible to both overburden removal and coal loading/hauling operations.

Each coal loader and hauler has different advantages. Of particular importance is the need to minimize the production of coal fines during the loading and hauling process. Coal

Table 2. Parameters and Their Definitions Applicable to Formulas Matching Equipment to Mine Design

Parameters	Description	Units
a	Angle of highwall	degrees
ABD	Annual burden demand	m ³ (cu yd)
ACP	Annual coal production	t (st)
b	Angle of spoil	degrees
BD	Overburden depth	m (ft)
BF	Bucket or dipper fill factor	.xx

TW	Truck width	m (ft)
"	Annual equipment utilization factor	.xx

loading equipment frequently is used to remove coal partings. The parting is either directly casted off coal or loaded into end-dump trucks for disposal in mined-out pit areas.

Equipment for surface coal mines is selected based on the numerous parameters discussed in this section. Various formulas that match equipment to mine design are given. The list of parameters and their definitions, applicable to these formulas, are given in Table 2. The parameters are illustrated in Fig. 22 and 23. Except for exponents, standard computer notation is used in formulas for ease of printing.

Frequently, mines are designed and equipment selected based on burden swell factors experienced at neighboring mines. For example, a lignite mine in the Texas Wilcox formation reports an average swell factor of 35%. Based on 35% swell, mine design indicates that the burden can be

removed with the operating dragline without rehandle. In actual operations, however, an extended bench method with 20% rehandle of burden is required to uncover coal. Why? The initial swelling of burden as it is dumped on the spoil by the dragline is much greater than the measured swell which probably is determined on an annual basis for management.

Knowledge of the settlement characteristics of spoil is necessary to ensure that mine design correctly defines conditions at the moment of spoiling burden. Settlement characteristics vary according to the material classification and hydrologic conditions. An analysis of the settlement characteristics of the burden at a Texas lignite mine estimated that 75% of all settlement occurs within one year after mining. Fig. 24 illustrates the settlement characteristics for the burden (Schneider, 1977). Based on an annual measurement of 35%, initial swell is more likely 45% or more. This difference in swell could represent approximately 3 m (10 ft)

†For basic stripping without chop down: $EBD = 0$, $HD/BD = 1$, $HC = 0$.

Fig 23. Minimum work width for coal shovel.

of additional dragline dumping height required in mine design.

Calculation of Utilization and Operator Efficiency Factors

In determining equipment productivity, it is common practice to discount operating time by applying an operating efficiency factor termed, "the 50-minute hour." This factor, equivalent to 0.833, is intended to include discounts for operator inefficiencies and minor operating delays. If operating conditions are abnormal, more discount is taken in terms of fewer "minutes per hour."

In the author's opinion, there are 60 min in every hour and the "minute-hour" factor has been used to account for inadequate analysis of the equipment operation. As equipment units have increased in size and unit capacity and as operating conditions vary, overdesign or underdesign of mining systems has resulted from this inadequacy.

With the advent of more refined engineering analysis made possible by computer application, it is possible to calculate many of the operating delays that affect productivity. In addition, time-motion studies can more appropriately assess the operator's efficiency without penalizing him for other operating delays.

Fig. 24. Thickness of a disturbed section and the percent of ultimate settlement recovered as a function of time since disturbance of an initial 30-m (100-ft) undisturbed section (Schneider, 1977).

Referring back to Fig. 20, Annual Schedule of Equipment Hours, operator efficiency assigns accountability to the operator only for those hours that can be productive.

While utilization is simply a measure of the ratio of time utilized to time scheduled, accountability for all delays that affect utilization is assigned to respective areas of responsibility. The utilization factor should be used in engineering design calculations and for equipment fleet sizing.

Coal Shovel Selection

$$BSP = [RCP/(3600/CT)](1 + SF)/(DC)(BF)$$

where

$$RCP = (ACP/CR)/(SH)(u)(OE)$$

Burden shovel can be selected by substituting

ABD for ACP, s for SF, DB for DC, with $CR = 1$.

Bucket size, BSP, is calculated in loose volume equivalent to in-bank (in-place) volume.

Minimum Truck Requirements for Coal Shovel

$$TLT = (TC/TPD)(CT)$$

where

$$TPD = (BSP)(BF)(DC)/(1 + SF)$$

$$FT = DT + MT + TLT$$

Therefore,

$$TCT = FT + (HDT/LS) + (HDT/ES)$$

and

$$NTR = [(TCT/TLT) \cdot u \cdot OE] + 1$$

Factors u and OE are assumed to be fleet averages. One truck is added, assuming all other trucks are in motion.

Minimum Working Width for Coal Shovel

$$MWS = SWDT + RCR + DOR + TW/2 + SWDS$$

or,

$$MWT = SWDT + 2TTR + SWDS$$

If MWS is equal, or less than the dragline panel width, it is selected. If the maximum designed dragline panel width is less than MWT, an extended bench method must be considered.

6.1 Drilling

6.1.1 Drilling Principles

HOWARD L. HARTMAN

INTRODUCTION

In virtually all forms of mining, rock is broken by drilling and blasting. Except in dimension stone quarrying, drilling and blasting are required in most surface mining. Only the weakest rock, if loosely consolidated or weathered, can be broken without explosives, using mechanical excavators (rippers, wheel excavators, shovels, etc.) or occasionally a more novel device, such as a hydraulic jet.

In the mining cycle, drilling performed for the placement of explosives is termed *production drilling*. Drilling is also used in surface mining for purposes other than providing blastholes. It finds application during exploration for obtaining drill hole samples and during development for drainage, slope stability, and foundation-testing purposes. Only in the production phase of surface mining, however, are unique or specialized drilling methods employed; the discussion in this section is directed primarily to that application of drilling.

There are minor applications of rock penetration in surface mining other than drilling. In quarrying, dimension stone is freed by cutting, channeling, or sawing. Usually mechanical means or sometimes a thermal jet is employed to produce a cut or kerf, outlining the desired size and shape of stone block.

A variety of geologic materials may be encountered in drilling. But whether they are ore or waste is usually of less consequence in selecting a drilling method than how resistant they are to penetration and how they occur geologically. The same drill may be used in overburden and in ore—but different drilling methods may be required in the same mine for markedly different ore or overburden formations.

Likewise, both consolidated and unconsolidated materials may have to be drilled. While soils and other loose materials do not require blasting, on occasion they may have to be penetrated by a drill when they overlie rock, or when they can be economically cast by explosives. The latter practice is termed *explosives stripping*, and is covered in the subsequent section on “Overburden Removal.”

This section is concerned primarily with the principles and engineering selection of drilling equipment to meet specified job requirements in surface mining, and secondarily with the drilling methods themselves. Following a presentation of the general principles of rock penetration, the remainder of the section considers the engineering application of the major types of production drilling equipment in surface mines.

CLASSIFICATION OF METHODS

A classification of drilling methods can be made on several bases. These include size of hole, method of mounting, and type of power. The scheme that seems the most logical to employ, a generic one, is based on the form of rock attack or mode of energy application leading to penetration.

Since drilling occupies only one category in the classification, the more general term *rock penetration* is preferred for all methods of forming a directional hole in rock. Hence it is preferable to speak of jet piercing as a method of thermal penetration rather than thermal drilling. *Drilling* is reserved for the mechanical attack systems.

The classification advocated here is a general one, applicable to all kinds of mining and encompassing all forms of rock penetration. Thus machines used for cutting as well as drilling are included. This classification bears some resemblance to one for rock fragmentation methods (such as blasting and other wholesale breakage techniques), since the principles are identical, and rock breakage is the common objective.

The known methods, based on rock attack, are listed in Table 1 in general order of importance today, with those having widest application appearing first. When a commercial or operational machine exists that employs a particular principle, it is so identified. An alternative classification, one employed by Maurer (1968, 1980), utilizes the rock disintegration mechanism (see “Analyzing Drill Performance” and Table 3).

Mechanical Attack

The application of mechanical energy to rock can be performed basically in only one of two ways: by percussive or rotary action. Combining the two results in hybrid methods termed roller-bit rotary and rotary-percussion drilling. The mechanical category, of course, encompasses by far the majority (probably 98%) of rock penetration applications today. In surface mining, roller-bit rotaries and large percussion drills are the machines in widest current use, with rotaries heavily favored.

Thermal Attack

Although penetration principles other than drilling are known, only two have been utilized commercially in surface mining. One is thermal penetration (the other is fluid). The only thermal method having practical application today is

Table 1. Classification of Rock Penetration Methods, Based on Form of Attack*

Form of Energy Application	Method	Machine
Mechanical (Drilling)	Percussion	
	Drop tool	Churn or cable-tool drill
	Hammer	Rock drill, channeler
	Rotary, drag bit	
	Blade	Auger or rotary drill
	Stone-set	Diamond drill
	Sawing	Wire-rope, chain, or rotary saw
	Rotary, roller-bit	Rolling-cutter drill
	Rotary-percussion	
	Hammer	Rock drill (independent rotation)
Thermal	Rotary	Rolling-cutter drill (superimposed percussion)
	Flame	Jet piercer, jet channeler
	Plasma	Plasma torch
	Hot Fluid	Rocket
	Fusion	Subterrene (Conceptual)
Fluid	Freezing	
	Jet	Hydraulic jet, monitor, cannon
	Erosion	Pellet-impact or abrasion drill
	Bursting	Implosion drill
Sonic	Cavitation	Cavitating drill
	Vibration	High-frequency transducer
Chemical	Explosion	Shaped charge, capsule, projectile
	Reaction	Rock softener, dissolution
Electrical	Electric arc or current	Electrofrac drill
	Electron beam	Electron gun
	Electromagnetic induction	Spark drill
Light	Laser	Electromagnetic radiation beam
Nuclear	Fission	(Conceptual)
	Fusion	(Conceptual)

* Energy applications listed in approximate order of present practicality. For classification by mechanism of rock disintegration, see Maurer (1980).

flame attack with the jet piercer or channeler. It penetrates the rock by spalling, an action associated with hard rocks of high free-silica content. Because of its ready capability of forming various shapes of openings, oxygen or air jet burners are used not only to produce blastholes but to chamber them as well and to cut dimension stone. Jet piercing of blastholes, however, has decreased in popularity in recent years as mechanical drills have improved in versatility and penetrability.

Fluid Attack

While disintegration of rock by fluid injection is an attractive concept, the end result is more likely fragmentation than penetration. To produce a directed hole with pressurized fluid from an external source, jet action or erosion appears to be more feasible, but commercial application to date is limited. Hydraulic monitors have been used for over a century to mine placer deposits and to strip frozen overburden; and more recently, high-pressure hydraulic jets have been applied successfully to the mining of coal, gilsonite, and other consolidated materials of relatively low strength. In one penetration/fragmentation device, hydraulic and mechanical attack mechanisms assist and complement one another. For large holes, the hydraulic jet alone may be competitive with drilling.

Sonic Attack

Sometimes referred to as vibratory drilling, this method as presently conceived is a form of ultra-high-frequency percussion. Attractive but not presently commercial, actuation of sonic devices by hydraulic, electric, or pneumatic means is possible.

Chemical Attack

Chemical reaction, because of the time element, may be more attractive as an accessory rather than a primary means of penetration. The use of explosives is a distinct possibility, however, and several alternative systems are under investigation. Additives to the drilling fluid, termed softeners, have shown some improvement in penetration rate in conventional drilling.

Other Methods of Attack

While some attempts to employ other forms of energy (electrical, light, or nuclear) have been made, the remaining methods in Table 1 must be classified in the experimental or hypothetical category at present.

Future Applications

Maurer (1980) among others is optimistic about the future of novel penetration devices, citing successful laboratory

and field tests where they have outperformed conventional drilling methods. It is probable, however, that their value for rock penetration in the near future will be limited to (1) supplementing mechanical energy (drilling) systems for special circumstances, and (2) creating very large or deep holes. Their application to general blasthole drilling in surface mining seems less attractive.

THEORY OF PENETRATION

Since the vast majority of rock penetration in surface mining is carried out by mechanical attack systems, the remainder of this section is devoted almost entirely to drilling.

Operating Components of System

There are four main functional components of a drilling system (and of most other penetration systems): (1) drill (energy source); (2) rod (energy transmitter); (3) bit (energy applicator); and (4) circulation fluid. These components are related to the utilization of energy by the drilling system in attacking rock in the following ways:

1. The *drill* is the prime mover, converting energy from its original form (fluid, electrical, pneumatic, or combustion-engine drive) into mechanical energy to actuate the system.
2. The *rod* (or drill steel, stem or pipe) transmits energy from the prime mover or source to the bit or applicator.
3. The *bit* is the applier of energy in the system, attacking rock mechanically to achieve penetration.
4. The *fluid* cleans the hole, controls dust, cools the bit, and at times stabilizes the hole.

In commercial drilling machines, attention has focused to some extent on reduction of energy losses in transmission. This has led to the introduction of down-hole (in-the-hole) drills, both of the large percussion variety and the roller-bit rotary (electro- and turbodrill) type, although the latter has found application mainly in oil well boring. They replace mechanical energy transmission with fluid or electrical transmission, which usually results in more energy reaching the bit and faster drilling.

Functions of Rock Drilling

A drilling (or any penetration) system must perform two separate functions in order to achieve advance into rock: (1) fracture and break material from the solid, and (2) eject the debris formed. The first phase is, of course, actual penetration, while the second is cuttings removal. Both affect drilling and drill performance but are distinct and separate functions of the process.

Mechanics of Penetration

As indicated earlier, there are only two basic ways to attack rock mechanically—by percussion and by rotation—and the four classes of commercial drilling methods to be discussed utilize these principles or combinations of them. It is the bit/rock interaction that governs the efficiency of energy transfer and the nature of the breakage process.

Fig. 1. Types of drilling action in mechanical attack on rock (after Maurer, 1967).

Causing rock to break during drilling is a matter of applying sufficient force with a tool to exceed the strength of the rock. This resistance to penetration of rock is termed its *drilling strength*; it is not equivalent to any of the well-known strength parameters. Further, the stress field created by the tool must be so directed as to produce penetration in the form of a hole of the desired shape and size. These stresses are quasi-static in nature, because forces are applied slowly in the drilling process. The inertia force, induced stress wave, and rate-of-loading effects in rock drilling have been demonstrated to be negligible (Maurer, 1962).

The different ways in which percussion, rotary, and combination drills attack rock are compared in Fig. 1.

Percussion Drilling: The *applicator* in a percussion drill is a chisel-shaped or button-studded tool that impacts the rock with a hammer-like blow. The stress effective in breaking the rock acts essentially in an axial direction and in a pulsating manner. Rotation enables the bit to strike the rock in a different spot on consecutive blows, a mechanism called *blow indexing*, which forms contiguous craters and ultimately a directed hole in the rock. The rotational torque applied, however, is usually not responsible for any penetration of the rock, since it is small in magnitude and, with rifle-bar rotation, is operative between blows only. Likewise, the sole function of the applied thrust is to keep the bit in contact with the rock.

The sequence in crater formation is as follows (Fig. 2): (1) the rock is inelastically deformed, with crushing of surface irregularities; (2) subsurface microcracks form from stress concentrations and confinement at the bit/rock interface enclosing a wedge of material, which is crushed; (3) secondary cracks propagate along shear trajectories to the surface, forming large fragments or chips; and (4) broken particles are ejected by the rebound of the bit and the cleaning action of any circulation fluid, resulting in the formation of a crater. The sequence is repeated with succeeding blows, except that indexing tends to provide additional "free faces" that may aid rock breakage and increase crater size. Indexing is not a sensitive variable, however, nor does it lend itself to precise control in drilling machines (Hartman, 1966).

Fig. 2. Cutting sequence of a percussion drill bit (after Hartman, 1959).

Fig. 3. Cutting sequence of a rotary drag bit (after Goodrich, 1957, and Maurer, 1967; by permission of The Curators of the University of Missouri).

In essence, insofar as rock fracture is concerned, the two predominant mechanisms in percussion drilling are crushing and chipping.

Rotary Drag-Bit Drilling: The planing or plowing action of a drag-type rotary drill bit is performed by a variety of tools, including blade and diamond drills as well as rope, chain, and rotary saws. Regardless of the geometry of the device, drag action at the cutting surface is supplied by two forces: thrust, a static load acting normally, and torque, the tangential force component of a rotational moment acting on the rock surface.

The mechanism of penetration in drag-bit drilling is as follows (Fig. 3): (1) as the cutting edge of the bit comes in contact with the rock, elastic deformation occurs; (2) the rock is crushed in the high-stress zone adjacent to the bit; (3) cracks propagate along shear trajectories to the surface, forming chips; and (4) the bit moves forward to contact solid rock again, displacing the broken fragments. One may conceive of the thrust as being responsible for indentation and the tangential force for plowing.

The similarity in cutting action of these two basic drilling systems is striking. One concludes that, under mechanical attack, rock fails alternatively by crushing and chipping, whether the energy is applied by percussion or rotation.

Rotary Roller-Bit Drilling: Essentially, the same form of drill rig may be used with rolling-cutter bits as with drag bits, employing the same forces to achieve penetration (although higher levels of thrust and torque are utilized, and heavier machines are customary). However, the geometry of the roller bit is such that a hybrid cutting action, a combination of percussion and rotary, results (Simon, 1956). As the bit turns, cutting teeth mounted on each rotating cone alternately engage the rock, impacting, indenting, and (with "soft-rock" bits) planing it (Fig. 4). The same crushing and chipping occur, however, as in the two basic systems; only the proportions differ.

Rotary-Percussion Drilling: This is also a hybrid form of drilling, combining independent percussive and rotational actions (Bullock, 1976). Generally, percussion bits (with buttons or asymmetric wings) or sometimes roller bits are used. In percussion drills of a down-hole design, independent ro-

tation is utilized, and the cutting action can be adjusted from straight percussion to rotary percussion. The superimposing of percussion on a rotary system means that higher impact forces are realized than in straight rotary drilling, but thrust and torque-induced forces are still operative. In rotary-percussion drilling, rock failure occurs by crushing and chipping, the proportion being a function of the drilling action.

Factors Influencing Drilling

A number of factors affect rock penetration or cuttings removal in the drilling process. These in turn largely determine the performance of a given drilling machine.

The various factors may be grouped in six categories: (1) drill, (2) rod, (3) bit, (4) circulation fluid, (5) drill hole, and (6) rock.

Those design factors in categories 1 to 4, components of the drilling system itself, are referred to as *operating variables*. They are controllable within limits, interrelated in some instances, and must be selected to match the environmental conditions reflected by category 6, rock type. Those variables of prime importance in the various drilling systems are listed in Table 2.

The *drill hole factors* of category 5, size, depth, and inclination, are dictated primarily by outside requirements and are independent variables in the drilling process.

The *rock factors* of category 6 are environmentally derived. They are also independent variables in the drilling process and include the following (Tandanand, 1973):

1. Material properties (resistance to penetration, porosity, moisture content, density, Shore hardness, compressive strength, coefficient of rock strength, etc.)
2. Geologic conditions (petrologic and structural-bedding, fractures, folds, faults, joints, etc.)
3. State of stress (in situ pressure and pore pressure—unimportant in shallow holes).

Another group of factors is external to the drilling process itself and may be referred to as *job or service factors*. These include operational variables related to labor, supervision, job site, scale of operations, power availability, and weather. While job factors are not involved in the mechanics of rock penetration, they may exert considerable influence on drill performance.

Fig. 4 Cutting sequence of a rotary roller bit (after Cheatham and Gnirk, 1967).

ANALYZING DRILL PERFORMANCE

For the operating details of application with a particular drilling method, the reader is referred to the latter part of this section. The discussion here is restricted to the basic aspects of drilling applications.

Performance Parameters

While more sophisticated criteria have been proposed, the following are adequate and employed almost exclusively in evaluating the performance of a given drilling system or in comparing different systems:

1. Energy or power
2. Rate of penetration
3. Bit wear
4. Cost

Under particular field circumstances, any one of these parameters may govern. In surface mining, energy or power consumption is becoming of increasing concern; but energies or powers, if compared, are generally of more concern because of their effect on penetration rate. Both penetration rate and bit wear are popular criteria, with rate more general in usage and wear more common for deep drilling where bit changes must be minimized.

But preeminent as a yardstick in any drilling situation is cost, for it collectively reflects all the other factors and is the ultimate measure of feasibility. A drill can have high availability and be novel, fast, and environmentally acceptable; but if it is not cost-effective, then an alternative system should be sought. (It is well to remember, however, that the goal in mining is the minimization of *all* rock breakage costs, and that drilling cannot be analyzed independently of blasting and comminution.)

Nevertheless, the first three parameters (energy, rate, and wear) enter into determination of the cost and largely control it. For this reason, it is desirable to know the quantitative, individual effect of pertinent operating variables (listed in Table 2) on energy, penetration rate, and bit wear, because they in turn determine the drilling cost.

Energy and Power: Formulas for determination of energy and power output in drilling systems are tabulated below, together with reference sources.

1. *Percussion* (Wells, 1950; Pfeider and Lacabanne, 1961):

$$\text{blow energy } E = \frac{1}{2} mv^2 = cWL^2B^2 \quad (1)$$

$$\text{power } P = BE = cWL^2B^3 \quad (2)$$

where m is piston mass = W/g , v is piston impact velocity, c is a constant = 0.3 to 0.5×10^{-6} (in English units), W is piston weight, L is piston stroke, and B is blow frequency. If the drill is pneumatic powered, then its energy and power output are most readily changed by varying the air pressure. Mathematically, the effect of gage air pressure p is

$$E \propto p \text{ and } P \propto p^{1.5}, \text{ since } B \propto p^{0.5} \quad (3)$$

$$\text{Thus, } P \propto p^{1.5} a^{1.5} L^{0.5} / W^{0.5}$$

where a is piston area.

2. *Rotary* (Teale, 1965):

$$\begin{aligned} \text{energy (work/revolution) } E &= E_f + E_r \\ &= Fh + 2\pi T \end{aligned} \quad (4)$$

$$\text{power } P = P_f + P_r = FR + 2\pi NT \quad (5)$$

where E_f is thrust energy, E_r is rotational energy, P_f is thrust power, P_r is rotational power, h is depth of penetration per revolution = R/N , R is rate of penetration, F is thrust, T is torque, and N is rotary speed (revolutions per unit time). Because the thrust component of the total energy and power in most rotary drills and boring machines is small (usually only 1% or less), the work done by the thrust is generally neglected (Roxborough and Rispin, 1972; Rowlands, 1974).

3. *Rotary percussion* (Inett, 1956; Bullock 1974):

energy and power:
percussion and rotary values additive.

Mining rotary-percussion drills of the hammer type are now usually hydraulically actuated, which permits higher efficiencies and increased power levels delivered to the bit.

One useful measure of the drilling efficiency of a particular machine is the *specific energy*, or the energy consumed per unit volume of rock broken (Teale, 1965; Bailey and Dean, 1967):

$$e = \frac{E}{V} = \frac{P}{AR} \quad (6)$$

where V is volume of rock broken and A is hole area. Specific energy varies with the drilling method, operating variables, drill hole geometry, and rock properties. As such, it is a sensitive measure of the effectiveness of a particular drilling system. It has also been shown by Tandanand (1973) to correlate directly with the coefficient of rock strength, compressive strength, and Shore hardness, all rock properties identified in "Theory of Penetration." A comparison of specific energy requirements for different drilling methods (plotted against hole size) appears in Fig. 5; in these tests, rotary percussion was most efficient.

Rate of Penetration: The rate of penetration for any drilling process is customarily expressed as a linear advance rate and may be defined by the relation:

$$R = \frac{\Delta V}{\Delta t} / A \quad (7)$$

where t is time and $\Delta V/\Delta t$ is the average volume rate of rock removal with respect to an interval of time. In drilling, the volume of rock broken has long been known to be directly proportional to the energy applied (Simon, 1956; Hartman, 1959):

$$V \propto E \quad (8)$$

neglecting the threshold energy to initiate penetration. Eq.

8 further yields the very important and frequently confirmed relation between rate of penetration and drill power (for a given bit size),

$$R \propto P \quad (9)$$

This is the basis for the repeated observation that, in a given system, *the only way to drill rock faster is to supply more energy to the bit.*

General relations for the various drilling systems can be developed from the specific energy (drilling strength) relation, Eq. 6 (Maurer, 1967):

$$R = \frac{P}{Ae} \quad (10)$$

At optimum conditions (peak efficiency), the minimum value of specific energy attained approaches the compressive strength of the rock being drilled (Teale, 1965).

Values comparing the specific energy, maximum power, and maximum potential drilling rate have been estimated for all the known methods of rock penetration and are given in Table 3, together with the applicable rock disintegration mechanism. While not precise, the data raise the interesting question of whether any other method of rock attack can penetrate rock more efficiently than mechanical attack. In fairness to the novel methods, however, Maurer (1980) points out that, in large holes where a kerf can be cut, a comparison of penetration efficiency and rate should be based on *specific kerfing energy*.

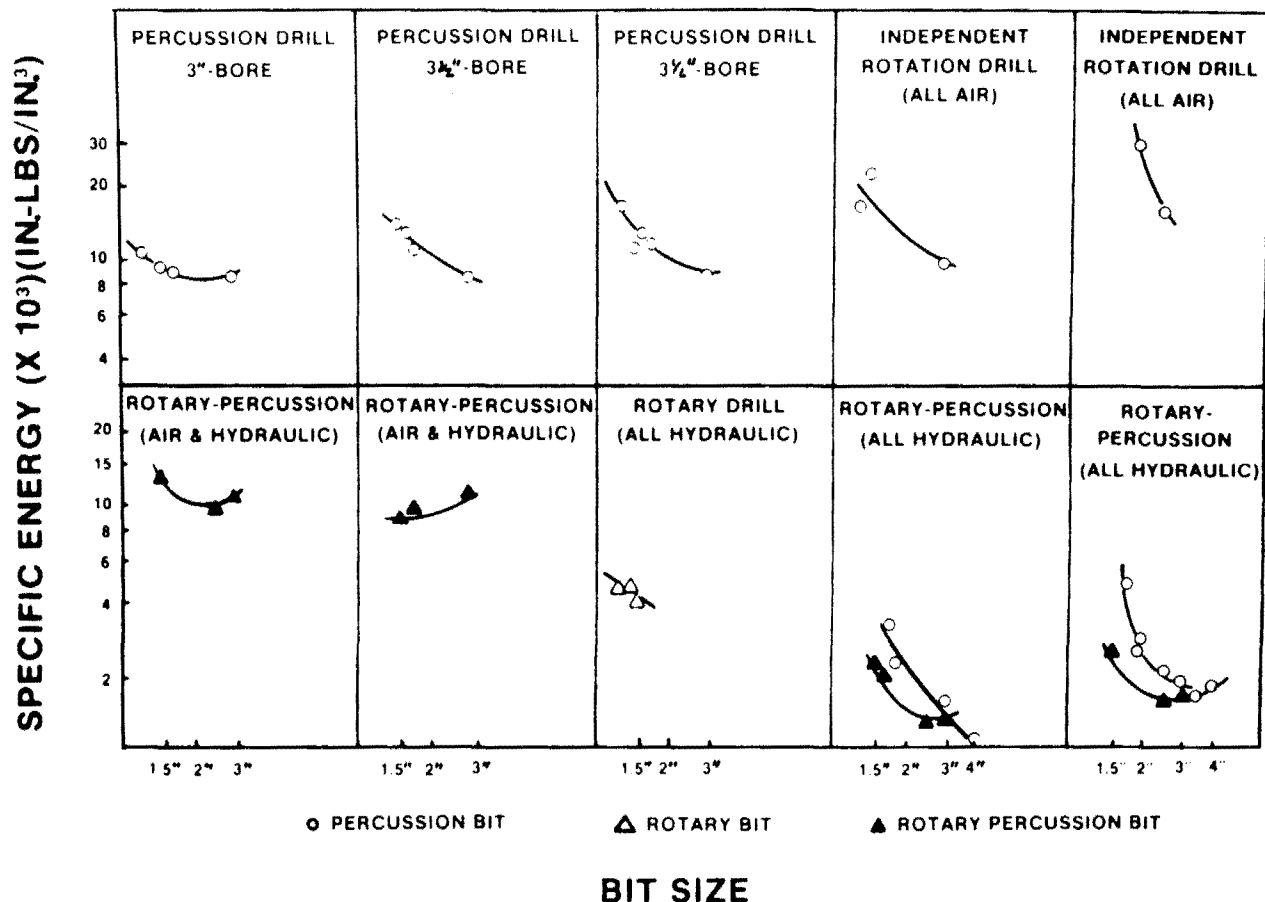

Fig. 5. Comparison of specific energy for different drilling systems; rock type: Bonneterre dolomite (after Bullock, 1976).

Table 3. Comparison of Specific Energy, Power, and Rate of Penetration for Different Methods of Rock Penetration

Penetration Device	Application	Rock Removal Mechanism	Specific Energy J/mm ³	Maximum Power to Rock, kW	Maximum Potential Penetration Rate mm/min
Rotary (roller bit)*	Field drill	Mechanical	0.2-0.5	15-20	140-850

[‡] Limited to highly spallable rock with high electrical conductivity.

[§] Limited to highly spallable rock with high magnetic susceptibility.

* 1000 mm diameter drill.

Formulas to determine rate of penetration for the three common rock drilling methods, incorporating theoretical or experimental parameters, follow.

1. *Percussion* (Hartman, 1959; Maurer, 1967):

$$R = \frac{BE}{Ae} \quad (11a)$$

$$R = \frac{V_c Bn}{A} \quad (11b)$$

where V_c is volume broken per cutting edge and n is number of bit cutting edges. Note that V_c , like e , must be determined experimentally. A more fundamental relation may be developed from Eq. 3 for pneumatic powered drills (Pfleider and Lacabanne, 1961):

$$R = \frac{k(pa)^{1.5}(L/W)^{0.5}}{Ae} \quad (11c)$$

where k is a proportionality constant. Again, values of k and e must be arrived at empirically.

Another factor that affects the performance of a percussion drill is thrust. Studies (Hustrulid and Fairhurst, 1972) have demonstrated that the value of thrust must be optimized to yield the maximum rate of penetration for a given set of operating conditions. The effect of thrust on penetration rate for varying air pressure is shown in Fig. 6; notice the optimal thrust levels, which can be estimated theoretically but are best determined experimentally.

2. *Rotary* (Teale, 1965; Maurer, 1967):

$$R = \frac{2\pi NT}{Ae - F} \quad (12a)$$

This equation follows from Eqs. 5 and 6. For most drag-bit drills, the thrust is small compared with other terms and may be neglected. With roller-bit drills, F is large and must be considered. Further, thrust and torque are interrelated in a rotary drill, and their effects cannot be considered independently.

a. *Drag-bit rotary* (Nishimatsu, 1972; Tandanand, 1973):

$$R = \frac{2\pi NrF \cot(\phi - \alpha)}{Ae - F} \quad (12b)$$

where r is effective bit radius, ϕ is angle of cutting friction, and α is rake angle of bit. This relation considers the effect of more variables and resolves the forces acting on a drag bit into vertical and horizontal components; however, it is more complicated to employ than Eq. 12a. The effect of thrust on penetration rate for different rock types is shown in Fig. 7.

b. *Roller-bit rotary* (Maurer, 1967):

$$R = \frac{V_c n_i N}{A} \quad (12c)$$

where n_i is number of tooth impacts per revolution. This formula follows from Eq. 7, but V_c varies for individual bit teeth. An empirical approach was taken by Simon (1956,

Fig. 6. Relationship between penetration rate and thrust as a function of operating air pressure; rock type: taconite (after Paone, Madson, and Bruce, 1969).

1967), who developed a series to relate the variables of roller-bit drilling:

$$R = k_1 \frac{NF}{De} \pm k_2 \frac{NF^2}{D^3e^2} \pm k_3 \frac{NF^3}{D^5e^3} \pm \dots k_n \frac{NF^n}{D^{2n-1}e^n} \quad (12d)$$

where $k_1, k_2, \dots k_n$ are constants. The relationship simplifies to the following for shallow holes and good cuttings removal (Maurer, 1962):

$$R = k \frac{NF^2}{D^2e^2} \quad (12e)$$

Fig. 8 demonstrates the relation of penetration rate to rotary speed and thrust; note that R is proportional to N only in the low range where good cleaning occurs.

3. *Rotary percussion.* Because it is a combination method in which variables interact, rotary-percussion drilling (like roller-bit drilling) does not lend itself to simple mathematical analysis. Rate of penetration is a function of drilling power and all the other variables operative in rotary and percussion drilling (Bullock, 1974, 1976). Drill performance is best determined by experiment.

4. *Jet piercing.* Thermal penetration with commercial jet piercers achieves advance chiefly by spalling. Rate of penetration is thus proportional to spallability. Although spalling is complex and not entirely predictable, a relationship can be used to estimate spallability (Calaman and Rolseth, 1968):

$$\text{spallability} \propto \frac{(\text{thermal diffusivity}) (\text{thermal expansion}) (\text{grain size})}{(\text{compressive strength})} \quad (13)$$

Fig. 7. Effect of thrust on drag-bit drilling rate for various rock types; bit diameter: $1\frac{1}{16}$ in., rotary speed 180 rpm (after Alpan, 1951-1952, and Maurer, 1967; by permission from the Institution of Mining Engineers).

Bit Wear: To date, there are no quantitative ways to relate bit wear or bit life to the operating variables in drilling. The term *wear* (actually, rate of wear) here refers to the loss of dimension, weight, or shape of cutting element in the bit unit time or length of hole. It is an inverse measure of the bit life, usually expressed in footage of hole, during which a tool is effectively and economically penetrating rock at an acceptable rate.

The mechanism of bit wear itself is not well understood. In percussion drilling, it occurs mainly as *impact wear*, and

Fig. 8. Effect of rotary speed and thrust on roller-bit drilling rate; rock: Beekmantown dolomite; downhole pressure: atmospheric (after Rowley, Howe, and Deily, 1961).

Fig. 9. Tooth wear vs. rotary speed for a roller bit (after Williamson, 1968).

in drag-bit rotary drilling, mainly as *abrasion wear*, with some mixed effect evident (Clark, 1982b). Combination effects occur in roller-bit rotary drilling and rotary percussion drilling, as would be expected. Percussion-bit wear has been described by Montgomery (1968) and Engel (1976) as microspalling. Drag-bit wear has been analyzed by Tandanand (1973) and Czichos (1978) as abrasion, adhesion, and surface fatigue. While concerned mainly with bearing life rather than tooth life, Burr and Marshek (1982) have attempted to quantify roller-bit wear. The effect of rotary speed on bit wear for sharp and dull roller bits is shown in Fig. 9; predictably, a sharp bit dulls more rapidly as N is increased.

The following wear relations are based on the major drilling variables and are empirical and qualitative only, with w some measure of bit wear.

1. *Percussion* (Inett, 1956; Larsen-Basse, 1973):

$$w \propto \frac{(\text{blow energy}) (\text{fluid viscosity}) (\text{rock hardness})}{(\text{cutting edge angle}) (\text{number of edges}) (\text{bit hardness}) (\text{fluid flow rate})} \quad (14)$$

2. *Rotary* (Goodrich, 1957; Fish, 1961; Tsoutrelis, 1969):

$$w \propto \frac{(\text{thrust}) (\text{rotary speed}) (\text{rock hardness})}{(\text{bit cutting angle}) (\text{bit hardness}) (\text{fluid flow rate})} \quad (15)$$

The primary effect of bit wear is to limit the application of a drilling method to rocks of acceptable hardness. In Fig. 10, it is very evident that drag-bit drills are operationally and economically feasible to operate only in soft and medium rock, while rotary-percussion and roller-bit drills are applicable to medium and hard rock. Percussion drills alone, however, are effective in very hard rocks.

Selection Procedure for Drilling Method

The selection of a particular machine for production drilling in a surface mine is the most critical kind of drill evaluation that the pit engineer is called upon to make. It is a true engineering design problem, requiring value judgments. Generally, the procedure follows these steps (Capp, 1962):

1. Determine and specify the conditions under which the machine will be used, such as the job factors (labor, site, weather, etc.), with safety the ultimate consideration.
2. State the objectives for the rock-breakage phases of the production cycle of operations—considering excavation and haulage restrictions, pit-slope stability, crushing capacity, production quota, pit geometry—in terms of tonnage, fragmentation, throw, vibrations, etc.
3. Based on blasting requirements, design the drill hole pattern (hole size and depth, inclination, burden, spacing, etc.).
4. Determine the drillability factors, and, for the kind of rock anticipated, identify the drilling-method candidates that appear feasible (manufacturers can perform rock drillability tests and recommend drills and bits).
5. Specify the operating variables for each system under consideration, including drill, rod, bit, and circulation fluid factors.
6. Estimate performance parameters, including machine availability and costs, and compare. Consider the power source and select specifications. Major cost items are bits, drill depreciation, labor, maintenance, power, and fluids. Bit wear and costs are critical but difficult to project.
7. Select the drilling system that, in best satisfying all requirements, has the lowest overall cost, commensurate with safe operation.

Items 4 and 6 are the most difficult steps to accomplish in the entire design procedure, primarily because of the present unreliability of drillability determination and drill performance prediction.

Table 4 is a qualitative attempt to aid in drill selection, relating application to rock type. The rating employs a relative scale of rock drillability (4 = highest), with corresponding examples. There is a prevailing tendency for the field of application of each method to expand toward the right, into more resistant materials.

The end point of the process is cost estimation (see the following section). While published data are not transferrable and quickly become obsolete, trends and ranges are significant. *In general, with off-the-shelf technology, the lowest costs are obtainable in soft rock with rotary drag-bit drilling, in medium and hard rock with rotary roller-bit and rotary-percussion drilling, and in very hard rock with percussion drilling.* In some rocks that are spallable, especially hard siliceous

rock, jet piercing may be economic. Hydraulic penetration appears promising for soft to medium rock. Rotary and percussion are sufficiently competitive in the medium-to-hard range to make the choice depend on particular circumstances, although the trend in surface mining is to roller-bit drilling for practically all rock conditions.

ACKNOWLEDGMENT

The author is especially grateful to his colleague and former student, Sathit Tandanand, US Bureau of Mines, Minneapolis, who contributed generously to the writing and editing of this section.

6.1.2 Drilling Application

ALAN BAUER
WILLIAM A. CROSBY

HISTORICAL DEVELOPMENT

Up until relatively recent times the principal method of blasthole drilling used percussive techniques. Early developments in the 19th century progressed from hammering on hand-held drill steel to steam-operated machines and then to piston-type drills. In 1897 J.G. Leyner introduced hollow drill steel to allow compressed air and water to be delivered to the drill bit to be used to flush the drill chippings clear of the hole. Two main types of percussion drills were developed: the piston drill and the hammer drill. In the piston drill, the drill steel was attached to the piston and both reciprocated and rotated. Piston drills now have largely been replaced by the hammer drill for percussion drilling. Drills currently in use employ pneumatic hammers either above ground or down-the-hole as well as the more recently introduced above ground hydraulic hammers. Percussion drill blastholes vary up to a normal operating size of 190.5 mm (7 1/2 in.) with some machines being used at 228.5 mm (9 in.) diameter.

After the Second World War, efforts to improve drilling productivity, particularly in hard drilling applications such as in taconite in the Mesabi Range, prompted the development of the rotary jet-piercing drill. At that time, rotary blasthole drills were not well developed and could not economically drill hard materials. The jet piercers enjoyed good success in hard spallable rock drilling for many years. With the development of the rotary drill, however, present-day use of the jet piercer drill has become extremely limited.

The techniques and principles of rotary drilling were to a large degree developed by the petroleum industry for the purpose of drilling oil wells to depths in excess of 6096 m (20,000 ft). Prior to about 1950, rotary drills were being used in mining but drilling was performed with drag bits confining the operations to soft materials such as those found in coal, porphyry copper, and soft natural iron ore mines. The replacement of water by air circulation to clean the blasthole and the introduction of the rotary tricone drill bit paved the way for major improvements in rotary drill performance. At the same time, the introduction of bulk, low cost explosives and the increasing demand for unit productivity did much to create a demand for larger blastholes. The result has been that, by far, the majority of all primary blasting in surface mines today is now being performed using rotary blasthole drills producing holes in the 165 to 445 mm (6 1/2 to 17 1/2 in.) size range.

PERCUSSION DRILLS

Percussion drills generally play a minor role as compared with rotary machines in surface mining operations. Their application is limited to production drilling for small mines, secondary drilling, development work, and wall control blasting.

There are two main types of drill mounting. The smaller machines utilize drifter-type drills placed on self-propelled mountings designed to tow the required air compressor. Typical hole sizes are in the 63 to 150 mm (2 1/2 to 6 in.) range (Fig. 1). The larger machines are crawler-mounted and self-

contained (Fig. 2). Drill towers permit single pass drilling from 7.6 to 15.2 m (25 to 50 ft) with hole sizes in the range of 120 to 229 mm (4 3/4 to 9 in.) in diameter. These larger machines are almost exclusively operated using down-the-hole hammers.

For many years these machines were exclusively operated using pneumatic hammers. In the last 15 years, hydraulic machines have been introduced in the smaller size range. The higher capital cost of these hydraulic drills is offset by lower operating costs and increased productivity compared with pneumatic machines. Another aspect that is becoming increasingly more important is the reduced noise produced by the hydraulic drills. The advantages of the hydraulic machines may be summarized as follows:

1. They are self-contained, diesel powered, and do not require an auxiliary compressor for drill operation.
2. The energy delivered in each stroke is markedly higher than for the pneumatic counterpart resulting in faster penetration rates.
3. The absence of exhaust air results in lower noise levels and reduced freezing problems as compared with pneumatic drills.
4. Energy consumption is reduced by up to 66%.
5. There is reduced machine and drill bit wear.

The surface-mounted percussive drill offers a number of advantages over down-the-hole drills. Surface-mounted drills often have higher penetration rates than down-the-hole drills in shallow holes at the same operating air pressure since the hammer piston area can be made larger than the blasthole area. For down-the-hole hammers, the piston area must necessarily be smaller than the blasthole area. Surface-mounted drills are attractive for secondary drilling work because they can drill smaller holes than down-the-hole machines, which are limited to a minimum size of approximately 100 mm (4 in.). Finally, the drill is never in the hole so there is no fear of it being lost in a caving hole.

On the other hand, for holes larger than 150 mm (6 in.), a down-the-hole machine is necessary. Energy losses in the drill string, particularly for all but the shallowest holes, contribute to decreased penetration rate with depth for the surface-mounted drills. The location of the hammer directly behind the drill bit in a down-the-hole machine means much lower energy losses regardless of the depth of hole. Furthermore, air used to operate the hammer is directly available to aid drill chip removal from the blasthole. Two other advantages of the down-the-hole machine as compared with the surface-mounted drill are the noise dampening effect of having the hammer in the blasthole and an increased life for drill rods and couplings as they are not required to transmit energy from the hammer to the drill bit.

Percussion Drill Productivity

Fig. 3 presents drill penetration rates plotted against hole diameter for percussive drills operating at low air pressures of up to 0.7 MPa (100 psi), drilling in materials of two different compressive strengths. It will be observed that penetration rate decreases with both increasing hole size and increasing rock strength.

Fig. 1. Self-propelled, hydraulic crawler-mounted drifter drill.

Blasthole drill productivity, regardless of the type of drill, is dependent on drill penetration rate and blasthole pattern size, which itself is dependent on hole diameter. As percussive drills are limited in hole size to a practical maximum of no more than 228 mm (9 in.) and few if any are used with greater than 190 mm (7½ in.) productivity improvements for these types of drill have concentrated on an increase in the penetration rate. Eq. (3) in the "Principles" part of this section presents the relationship between penetration rate and piston area, weight and stroke length as well as operating air pressure. As the piston area and stroke length are fairly inflexible for a given hole size, one main thrust to help improve percussive drill productivity has been to improve the drill penetration rate by increasing the hammer operating pressure. A typical increase in penetration rate experienced when changing from 0.7 MPa (100 psi) to 1.7 MPa (250 psi) would be of the order of 200% with an approximate doubling in the actual hole production rate.

Some attempts have also been made to improve drill penetration rate by using high frequency blows. However, it has been found difficult to hold the hammer together using this approach, especially at the higher air pressures.

The other option is to use hydraulic machines to improve the energy available at the drill bit. Table 1 presents a detailed test comparison between one hydraulic drill and eight pneumatic machines drilling a fine-grained, dense hornfels having a compressive strength of the order of 200 MPa (30,000 psi). The penetration rate for the hydraulic drill is shown to be from 20 to 100% higher than the pneumatic machines.

Percussion Drill Costs

Fig. 4 presents cost vs. blasthole size for percussive drills operating up to 0.7 MPa (100 psi) air pressure in the same materials as compared in Fig. 3. As for the penetration rate, the costs are dependent on both the blasthole size and the strength of the rock.

Fig. 5 compares the cost for two sizes of hammer drill with a medium-sized rotary machine. This comparison is made for hammer drills operating with 0.7 MPa (100 psi) air pressure. The high cost for hammer drilling is partly a result of lower penetration rates obtained as compared with rotary machines (Fig. 6). While an increase in operating air pressure has greatly improved blasthole penetration rates, the drilling cost improvements have been less impressive because of higher maintenance costs, lower machine availabilities, etc. The result is that high pressure 178 mm (7 in.) hammer drilling cost is approximately 100% higher than 250 mm (9½ in.) rotary drill per unit volume of material blasted.

A comparison between pneumatic and hydraulic surface-mounted drill costs follows:

	Pneumatic	Hydraulic
Investment cost	1.0	1.27
Energy cost	1.0	0.24
Drill steel cost	1.0	0.86
Overall operating cost	1.0	0.78

A complete operating cost comparison between the two drill types is presented in Table 2.

Fig. 2. Self-contained, crawler-mounted, down-the-hole hammer drill.

JET-PIERCING DRILLS

The jet-piercing process relies upon a characteristic of rock known as spallability. The rock is broken down, or spalled, as a result of differential expansion of the rock crystals by thermally induced stresses. The jet-piercer drill essentially consists of a burner fixed to a blowpipe that produces a high temperature flame (of the order of 4300°F) with a high velocity of approximately 5000 fps by burning fuel oil in oxygen. The burner is directed into the ground in the same manner as a rotary drill bit using the blowpipe, with drills having a typical drilling depth capability of 15.2 m (50 ft). In addition to fuel oil and oxygen, water is also used to cool the burner and, in the form of steam, it helps eject the spalled rock cuttings from the blasthole. Hole diameters range from a minimum of approximately 229 mm (9 in.) up to 457 mm (18 in.) using chambering burners.

As stated in the introduction, very few jet-piercer drills are now in operation. One of the main problems with the system has been the high cost of oxygen and fuel oil, which

has helped to make the drill uneconomic. Other disadvantages to the drill include the difficulty of supplying the process fluids (particularly in cold climates), and the irregular blast-hole profile that makes consistent blast design difficult.

For detailed discussion on jet-piercing, the reader is referred to the first edition of *Surface Mining*, Chapter 6.4 by Calaman and Rolseth (1968).

ROTARY DRILLS

In rotary drilling, the drill bit attacks the rock with energy supplied to it by a rotating drill stem. The drill stem is rotated while a thrust is applied to it by a pull-down mechanism using up to 65% of the weight of the machine, forcing the bit into the rock. The drill bit breaks and removes the rock by either a ploughing-scraping action in soft rock, or a crushing-chipping action in hard rock, or by a combination of the two.

Compressed air is supplied to the bit via the drill stem. The air both cools the bit and provides a medium for flushing the cuttings from the hole. Water may be used in addition

Fig. 3. Penetration rate vs. hole diameter for percussive drills operating at low pressure.

Fig. 4. Cost vs. hole size for percussive drills operating at low pressure.

to the compressed air to suppress the effects of dust, however, this is normally found to have a detrimental effect on bit wear. Blashole sizes produced by rotary machines vary in the range of 100 to 445 mm (4 to 17½ in.) diameter with the most common sizes being 200, 250, 311, and 381 mm (6⅞, 7⅞, 9⅞, 12¼, and 15 in.). These drills usually operate

in the vertical position (Figs. 7 and 8), although many types can drill up to 25 or 30° off the vertical. Drills are manufactured that can drill horizontal holes used in overburden stripping where hard bands of material are located low in the highwall face. This technique eliminates wasteful and difficult vertical drill footage through soft materials.

Fig. 5. Comparison between hammer and rotary drill costs.

Rotary Drill Penetration Rate

One of the most important factors in drilling is how fast can drill hole be produced while the machine is actually drilling. This factor almost entirely influences productivity and has a strong influence on unit costs. It will, therefore,

be used as a starting point for this discussion of some of the important aspects of blasthole rotary drilling.

Several years ago, extensive field surveys were conducted in the iron ore industry in North America with a view to relating rotary drill performance to rock properties. These studies (Bauer and Calder, 1966) showed that a good correlation could be obtained between penetration rate and rock uniaxial compressive strength, provided sufficient tests were conducted to obtain a sufficiently meaningful rock strength. Instrumented field tests also indicated that the penetration rate could be correlated linearly with the weight/inch of bit diameter and with the rotary speed. The results of this work

Fig. 7. Large electrically powered rotary drill.

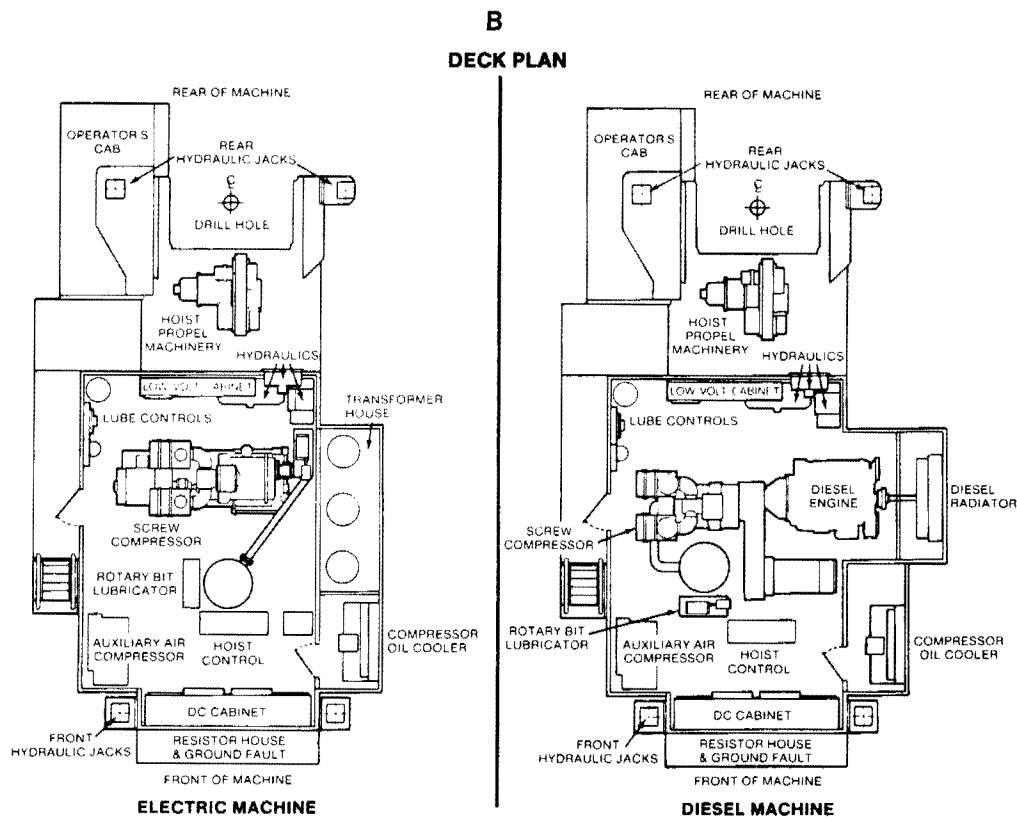

Fig. 8. Large rotary drill elevations (A) and deck plans (B) for an electric and diesel machine.

can be expressed by the following empirical equation (Bauer and Calder, 1967),

$$P = (61 - 28 \log_{10} Sc) \frac{W \text{ rpm}}{\phi \cdot 300}$$

where

P = penetration rate (ft/hr)

Sc = uniaxial compressive strength, in thousands of psi

W/ϕ = Weight per inch of bit diameter, in thousands of pounds

rpm = revolutions of drill pipe per minute.

Laboratory indenter tests also give an initially linear force penetration relationship when tungsten carbide inserts are pushed into rocks of different strengths. The slope of these graphs can be related to the rock compressive strength or crushing strength.

Of the factors in this equation, the rock compressive strength is uncontrollable for a given mine whereas the rotary speed and pull-down can be varied by the drill operator. Fig. 9 illustrates penetration rate as a function of rock compressive strength for a rotary speed of 75 rpm and the recommended bit loading. The relationship holds well for most rock strength values, although for the very soft materials, penetration rates increase markedly above those that would be anticipated by extrapolating values from Fig. 9.

Rotary Drill Rotation Speed

The rotary drive motor turns the drill tool string thus turning the drill bit at the bottom of the hole. This action brings the successive lines of drill bit compacts into contact with the base of the hole. As the rotary speed increases, so does the number of contacts and the penetration rate. The limit to rotary speed is hot bearings in the bit or stripping of the heel row compacts. Current rotary speeds range from 60 to 90 rpm for hard materials with greater speeds for softer rocks.

The limitation on penetration rate at many mining properties is the rotary horsepower available. The horsepower requirement can be estimated using the empirical equation:

$$hp = K \cdot \text{rpm} \cdot D^{2.5} W^{1.5}$$

where

D = bit diameter (in.)

W = weight on the bit in thousands of pounds

K = constant that varies with rock type. As material strength decreases, the value of K increases. This caters for the greater teeth penetration experienced in soft rocks. Values vary from 14×10^{-5} for soft rocks down to 4×10^{-5} for high-strength materials.

The other important aspect as regards the rotary power requirement is the method of stabilization. The type of stabilizer, or for larger holes, whether stabilization is used at all, will greatly affect the rotary horsepower requirement and thus the penetration rate in most materials.

Rotary Drill Pulldown Weight

A portion of the machine weight is applied by the pull-down motor via the pulldown chain or chains, rotary head and drill stems to the drill bit. Fig. 10 illustrates recommended bit loadings for different bit sizes. As the bit diameter increases, the bearing size increases thus allowing an increase in the tolerable load. Overloading the bit results in severe loss of bit life as illustrated in Fig. 11.

Rotary Drill Bits

The tricone rotary drill bit has evolved from the drag bit and two cone bits. Fig. 12 illustrates the various components of a mill tooth bit.

Mill, or steel tooth bits are used for soft rock with the cutoff being a medium-strength limestone. Tungsten carbide bits are used for all harder rocks.

Figs. 13 and 14 illustrate the effect of rock strength on bit life for various bit sizes.

The larger bit sizes, incorporating larger bearings, etc., can be expected to give higher footages per bit. This has not always proved the case. Table 3 presents footages currently being experienced by a large Canadian iron ore operation.

These footages are averages for the highest-grade tungsten carbide bits of different manufacture, the ore having variable

Fig. 9. Penetration rate vs. rock strength for various hole diameters at recommended weight per inch of bit, at 75 rpm

Fig. 10. Recommended pulldown weight per inch of bit diameter vs. bit diameter.

compressive strengths averaging approximately 204 MPa (30,000 psi). As can be seen the values are completely reversed from what may be expected, introducing another important factor in the drill operation (which also affects penetration rate) the air supply and bailing velocity.

Fig. 11. Bit life vs. pulldown weight for 250 mm (9 7/8 in.) diameter tungsten carbide rotary bits in a hard formation.

Rotary Drill Air Requirements

Air is used to bail the drill cuttings from the hole as well as cool the bit bearings and, when used, roller stabilizer bearings. Approximately 20% of the air is forced through the roller cones for cooling purposes by adjusting the air pressure across the bit using the bit nozzles.

The air volume is the primary requirement for bailing cuttings from the hole. Air velocity up the hole is dependent on the air volume per minute as well as the hole annulus. Tables 4A and 4B illustrate the various velocities obtained for hole, pipe size, and compressor combinations.

The velocity of the drill cuttings in this air is dependent on the chip size, density, and shape. Experimentally, the balancing air velocity in feet per minute is given by:

$$Um = 264 p^{1/2} d^{1/2}$$

$$= 2420 \text{ fpm for } 13 \text{ mm (1/2 in.) diameter}$$

platelets with a density of 2.7 g/cc.

d = diameter of the chip in inches

ρ = density of chip in lb/ft³

At air velocities above this balancing value, the chips begin to move, their velocity being approximately one half the excess air velocity above the balancing value. A bailing velocity of 1800 mpm/s (6000 fpm) is usually adequate to bail 13 mm (1/2 in.) chips. Fig. 15 illustrates a typical air requirements chart.

Factors involved with choosing the air velocity are that higher velocities:

1. give higher bailing velocities;
2. will bail larger chips;
3. tend to give higher bit life;
4. will help cater for hole cavities, etc.;
5. will help cater for drill stem wear;
6. may give higher penetration rates and possibly lower cost per ft; and
7. reduce the volume of cuttings in the hole for a given penetration rate;

But they

1. will give increased stabilizer and pipe wear;

Fig. 14. Steel toothed rotary bit life vs. diameter for two rock strengths.

- will give increased dust deflector and deck bushing wear; and
- may damage borehole walls in soft drilling.

A further consideration when selecting the air volume is the altitude at which the drill will be working. Table 5 presents the compressor altitude multipliers that should be used to compensate for increased mine elevation above sea level.

Most new drills are now purchased with rotating screw compressors that tend to give lower drill bit life as a result of poor lubrication as compared with the vane compressor. Many mines have achieved much increased bit life by adding lubrication oil to the drilling water. One large copper mine in Africa has obtained a doubling of their 311 mm (12 1/4 in.) drill bit life by using 7 L/hr oil in 9 L/min water with air at 23 m³/min.

Rotary Drill Stems

Other factors involved when selecting drill stems (apart from the bailing velocity consideration) include: (1) fabricated or integral drill steel; (2) thread size and type; (3) wall thickness; and (4) types of connection.

High wear occurs behind the bit as this is a turbulent air zone. Also the section of rod just behind the bit is in the hole the longest. Once wear begins in this area, it will be further accentuated by the increased annulus further disturbing the air flow. The use of two box ended rods helps to reduce this type of wear by offering the opportunity to up-end the rods in addition to the usual exchange practice.

Rotary Drill Stabilizers

There are two main types of stabilizer on the market, the blade and roller.

Blade type stabilizers are generally cheaper in terms of initial purchase price but require rebuilding for each drill bit. In hard ground they give very poor stabilization after one or two holes have been drilled. A relatively high rotary torque is required in comparison with the roller stabilizer. Replaceable wear bars and sleeves can be used to speed up rebuild and help to reduce stabilization costs.

The roller stabilizer can be a throwaway or replaceable roller type. Lower rotary head torque is required for operation and stabilization is generally better than that provided by blades. The throwaway type have larger rollers, (no rebuild pin assembly, etc.) and usually give more economical life.

Experimental stabilizers include: (1) roller stabilizer with nonrotating outer casing; (2) chamber reamer; and (3) hole reamer stabilizer using a smaller pilot bit.

For larger drill bit sizes, 311 mm (12¼ in.) and up, some operations dispense with stabilization, thus eliminating the loss of rotary horsepower.

Rotary Head Shock Subs

In recent years rotary head shock subs have been developed by a number of manufacturers in order to reduce drill vibration, cut maintenance costs, and increase drill availability and bit life. The shock sub is essentially a large shock absorber which is fitted between the drill and drill pipe on top-drive machines. Shock subs are designed as follows:

1. *Type A (Swivel Mounted)*. This consists of an adapter mounted element incorporating eighteen segments, each consisting of two heat treated alloy steel drive lugs molded together with rubber. These segments are retained by end plates to which the adapters fasten.

Fig. 15. Air requirements chart.

2. *Type B (Gas Spring)*. This works on a gas spring principle using nitrogen under pressure to achieve a soft spring.

Several operators report that machine maintenance costs have been reduced up to 18%, drill availability increased by up to 7½%, noise levels have been reduced (in one reported case from 120 to 84 db), and penetration rates and bit life increased considerably.

Table 5. Multipliers for Air Consumption of Drills at Various Altitudes

Multiplier	0	1.03	1.07	1.10	1.14	1.17	1.21

Cold Weather Operation

Drills to be used in cold climatic conditions should be purchased with a cold weather package.

In construction, high stress or impact areas should be manufactured using normalized steel having good notch toughness at cold temperatures. For operator comfort, double or triple glazing and additional insulation in the cab are useful along with additional heating capability as compared with regular machines.

Additional heating is also required for the machinery house to assure adequate start-up. Heated water tanks and lines are required for the water injection system if used. A special blowdown system is necessary to purge water lines for stand-down periods. An auxiliary diesel generator is commonly employed to run heaters should the drill come off power.

If a screw compressor is in use, a system is required to remove radiator oil at the end of use so that it is not full of cold stiff oil upon start-up. In extremely cold climates, the radiator compartment would be heated to ensure the oil will flow. For the auxiliary air systems, an efficient air drier is required to remove water from the supply lines to the high pressure air controls.

Finally special oils should be selected for the gear cases, compressor operation, etc., when the drill is put into operation.

Single Pass Drilling

In the late 1960s and early 1970s, many new mining ventures selected bench heights and drill equipment to utilize single pass drilling. Some of the older mining companies are now converting drills to single pass by adding extended masts and/or changing bench heights. The use of extended masts has been facilitated by the increase in hole size allowing the use of larger diameter steel and thus eliminating the need for center guides. Tool strings are now available to drill 20.1 m (66 ft) holes with mast heights greater than 27.4 m (90 ft).

Advantages of single pass are:

1. eliminates adding stems;
2. reduces associated thread damage;
3. reduces machine downtime for rod changing equipment and tool racks;
4. facilitates the cleaning of boreholes;
5. permits a continuous air flow through the bit at all times. This is especially important in wet holes as it eliminates the possibility of siphoning water and drill cuttings up into the bit.

Disadvantages of single pass are:

1. high masts make the drill more unstable (especially for the predominantly rotary head drive machines); back braces become almost mandatory;
2. extra care needs to be taken when moving the drill over medium or long moves,

3. pulldown chains become long and may require special attention.

For operations choosing to reduce bench height in order to attain single pass drilling, the following other benefits may also be experienced:

1. multirow blasts become easier to blast;
2. drill cuttings volume is reduced (especially important for the larger holes);
3. ramp volume is reduced (when fill ramps are used);
4. contour areas are easier to drill and blast;
5. ore grading is easier.

However poor control of the shovel grade is accentuated.

Rotary Drill Productivity and Costs

Fig. 16 presents typical rotary drill productivity for different hole sizes drilling different material types. Fig. 17 gives the drilling cost per unit length of hole for different hole size. Finally, Fig. 18 combines these graphs to present the unit cost for drilling using different hole sizes for different rocks.

The drilling cost is made up of two different parts, the drill consumables per unit length of drilled hole and the balance of the drill cost. The balance of the drill cost is converted to the drill cost per unit length of hole using the drill penetration rate. The reason for this split is that the drill consumables cost, predominantly the drill bit cost, is independent from the drill penetration rate, assuming correct operating methods, whereas all other costs are penetration rate dependent. Regarding drill records, it is, therefore, equally important to keep the penetration rate achieved by a drill bit as well as its life. This is particularly true in drilling soft materials where drill bit costs can be very low.

Drilling Trends

Rotary drills have increased their dominance of blasthole production in open pit mining. The trend has been to larger sturdier drills, to yield higher mechanical availability and operating performance. The increased availability has been

Fig. 16. Tons drilled per operating hour in different materials using rotary drills of different hole diameter capability.

Fig. 17. Drilling cost for rotary drills drilling holes of different size.

achieved by improvement of crawler track frames, masts, propel chains, pulldown mechanisms, rotary head drives complete with automatic lubrication and greasing, on the new models of machine. Drill pipe feed rates have been increased so that pulldown weight can also be applied in very soft formations that fail easily and the penetration rates increased in such applications. Increased rotary drive horsepower and improved mast designs have permitted higher rotational speeds, which have in turn permitted higher penetration rates and lower costs to be achieved in many instances. The improved mast designs permit the use of higher speed drilling by reducing vibration on the drill.

Productivity improvements have been tried by using chambering or reaming drill bits. Techniques that have been tested include drill bits having extendable arms that could

increase the hole diameter at depth. None of these techniques to date has proved successful on a practical and economic basis.

Improvements have also been attempted in the weight distribution on the drills so that a higher percentage of the gross machine weight can be used for generating pulldown; the improved mast design on some of the models also helps to serve this purpose by putting more weight over the drilling tools.

It is noteworthy that the trend has been to larger and larger drills with increased pulldown weight capability. In very hard rock drilling, the larger machines are being used at a hole size that is well within their capability and therefore the machine is not taxed; this results in less breakdown and increased performance. Since the penetration rate is propor-

Fig. 18. Drilling cost per ton vs. hole size in different rocks.

Fig. 19. Penetration rate vs. hole diameter for rotary drilling in hard iron ore [compressive strength, 200 MPa (30,000 psi)].

tional to the rpm and the weight/length of bit diameter, the bit technology has been to improve bearings, cone structure, and carbide quality for hard rock drilling. This has allowed the W/ϕ and rpm to be increased to increase performance. At the same time, bit life has not decreased, or, at least, not to an extent that the gains due to the penetration rate increase have been negated. For example, in North America in hard drilling, bit costs can represent up to 60 to 65% of the total operating cost on the drill so that if increases in penetration rates are accompanied by decreases in bit life, it is not nec-

essary for the bit life to decrease too far before any gains due to productivity increase are cancelled. In such operations considerable attention must be paid to penetration rate and bit life to produce the minimum cost/foot of hole. In soft formations, the bit cost only represents approximately 10% of the total drilling cost per unit length so that one can tolerate a significant decrease in bit life for increases in productivity and still gain financially.

Depending on the material type and hole size, rotary horsepower is proportional to (rpm)·(weight/in. of bit di-

Fig. 20. Production rate vs. hole diameter in the same hard iron ore.

ameter)^{1.5}. To double the rpm capability of the machine under the same load conditions, it is necessary to double the rotary horsepower. Future developments should come in this area since it seems entirely feasible with suitable rotary head modifications to double rpm capability, which would double production capability.

In iron ore mining 250, 311, and 381 mm (9 $\frac{7}{8}$, 12 $\frac{1}{4}$, and 15 in.) diameters are standard sizes of hole, with the two smaller sizes being in the majority. The percentage of 381 mm (15 in.) holes has been continually increasing. This larger hole size was initially used in the softer formations and in higher tonnage operations where ore grading requirements are not a problem. Today this has changed and 381 mm (15 in.) holes are being used in the hardest formations.

Productivity has also been increased significantly at most operations with hole size increases. Larger bits have larger bearings and can accept higher loadings and still give satisfactory life. In going from 175 to 250 mm (6 $\frac{7}{8}$ to 9 $\frac{7}{8}$ in.) bit sizes, the operating weights increase from 89 to 116 kg/mm (5000 to 6500 lb/in.) of bit diameter for hard formation drilling. With similar rotary speeds, this produces a penetration rate increase of approximately 30%. Bit sizes larger than 250 mm (9 $\frac{7}{8}$ in.) are being run at 107 kg/mm (6000 lb/in.) of bit diameter in order to maintain adequate bit life, which often represents 60 to 65% of the total operation cost of the drill in hard formations [compressive strength 200 MPa (30,000 psi) or greater]. Holes of 381 mm (15 in.) diameter can be drilled almost as quickly as 250 mm (9 $\frac{7}{8}$ in.) holes and, when scaled for the tonnage increase per hole, this represents a significant productivity increase.

In softer formations or formations in which the fragmentation is preformed, patterns have generally increased in proportion to the diameter of the hole so that in going from 311 to 381 mm (12 $\frac{1}{4}$ to 15 in.) holes, productivity has often increased by approximately 40% and there has been a corresponding decrease in cost/ton. In hard massive formations, the productivity has been increased but not to the same degree. Recently 445 mm (17 $\frac{1}{2}$ in.) diameter holes have been tested at two locations, as a desire to extend the productivity increases and economic gains. The results were relatively poor. More recently, work on the Mesabi Range has shown some productivity advantage of this large hole drilling and blasting in hard rocks with preformed fragmentation, but the economic advantage has yet to be seen due to bit technology lag. In Labrador, 381 mm (15 in.) diameter blastholes are being used successfully in hard [270 MPa (40,000 psi), compressive strength] massive quartz, magnetite, and specular hematite.

Fig. 19 presents the drill penetration rate vs. hole size in a hard massive low-grade iron ore, and Fig. 20 shows the actual productivity obtained at one Canadian mine in going from 250 to 311 mm (9 $\frac{7}{8}$ to 12 $\frac{1}{4}$ in.) to 381 mm (15 in.)

Fig. 21. Total drilling and blasting costs for the same fragmentation using holes of different diameter in the same hard iron ore.

diameter blastholes on the same size of drill. This represents a productivity increase of 73%. Fig. 19 also contains the equivalent blast patterns for excellent fragmentation using a 10% aluminized TNT slurry, and 0% aluminized TNT slurry, and based on 63.5 Mt (70 million st) mined at the larger hole sizings. Pit floor digging of the large hole blasts is eased significantly due to the higher concentration of energy in the toe of the blast. This has resulted in higher shovel productivity. Fig. 21 shows the total direct drilling and blasting costs, which were reduced from 32¢ to 27.5¢/ton. Machine capital cost savings also accrue due to the productivity increase.

6.2 Blasting

6.2.1 Blasting

ALAN BAUER
WILLIAM A. CROSBY

INTRODUCTION

Most rocks require blasting prior to excavation in surface mining operations. Blasting is the most important of the unit operations for many mines because if it is not performed successfully, the viability of the mine frequently becomes jeopardized.

The principal factors that influence blasting results are the properties of the explosives being used, their distribution and initiation sequence in the blast, the overall blast geometry, and the rock structure and other properties. This section indicates the effects of these different factors and describes suitable blast design techniques. In addition, specialized blasting methods such as throw blasting and wall control are discussed along with some of the detrimental aspects of blasting, vibration, air blast, and noise.

EXPLOSIVES

There are four main types of explosive used in surface mining: slurries, dry mixes, emulsions, and the hybrid heavy ANFO. These products will be considered separately.

Blasting Agents Development

Historically, prior to the *lease-lend* fertilizer disasters at Texas City and Hamburg in the 1940s, ammonium nitrate (AN) and fuel was not being used in bulk form as a blasting agent. Its use up to that time primarily was in canned explosives which used blends of AN to increase the density, cheap fuels such as Bunker C, and densifying agents such as ferrosilicon. Because of the viscosity of the Bunker C fuel, these mixes were often made hot. The cost was high due to the use of the cans and the canning process. Although the density was about 1.1 g/cm³, the bulk strength was low due to the large annular space around the can when it was loaded into the borehole. Pelleted TNT was often put into the holes to surround the lower cans and to reduce the effect of the decoupling in the toe. The other explosive in use was dynamite.

During the early 1950s AN mixed with fuel oil was introduced to the blast site as a bulk explosive. In many instances it proved to be ideal, but it did have its drawbacks. These mainly revolved about its lack of water resistance and low bulk density, which in turn produced a low bulk strength.

By the mid 1950s, the drilling and blasting of very hard iron formation at Schefferville in north-eastern Quebec, with its attendant very high drilling costs and wet conditions, prompted Cook and Farnam to set out to invent explosives having good water resistance and high bulk strength. Initially two systems were developed, both using AN and water, with one system based on TNT or other high explosives as the sensitizer, and the other which used fine suitably coated aluminum for the same purpose. The basic high explosive (HE) sensitized slurry consisted of ammonium nitrate, water, thickeners, and the HE (TNT) sensitizer. The quantity of TNT used varied, depending on the critical diameter desired

and the temperature likely to be encountered. However, for a critical diameter of 75 mm (3 in.) at 0° C, a typical composition would be approximately 25% TNT, 15% water, 59% AN, and 0.5 to 1.0% of gum thickener. The gum thickener served two purposes: first, it held the coarse high density TNT in suspension and second, it formed a jellylike continuous matrix which imparted good water resistance to the slurry if the gum was suitably crosslinked. Energetic metal fuels such as aluminum were soon added to these slurried explosives to increase their bulk strength further. The basic TNT slurry had a density of approximately 1.45 g/cm³ and a weight strength relative to ANFO of 85%, so that its bulk strength was 1.48 relative to free poured porous prills and fuel oil. This meant much greater toe pulling capability and in many instances larger drilling and blasting patterns. The explosive cost was sometimes increased, but the reduction in drilling cost often made up for it and the net result was an overall reduction in drilling and blasting costs with better results.

Nitro-carbon nitrate (NCN) aluminum-based slurries had been developed but these were not rushed into production immediately in Canada on account of the climatic conditions in the northern part of the country. Borehole temperatures run as low as -2° C and temperatures on the benches periodically as low as -45° C with -20° to -30° C for extended periods of up to several weeks.

More recently fuel oil air bubble sensitized slurries were introduced to replace ANFO where holes cannot be dewatered. Phosphates and other coating agents were introduced to stop the aluminum from gassing, and also to prevent the pH changing, thereby breaking down the gel. Fig. 1 shows the general class of blasting slurries.

By the early 1960s slurry had been well tested in many areas and there was a considerable demand by mine operators, many of which were loading at levels of approximately 25 000 kg/d (55,000 lb/per day), which made packaging expensive. Transportation was also a costly item since the explosive plants were often remote from the mines. This meant that all of the ingredients in the packaged TNT slurry travelled at the high explosive freight rate. A minimum of 15% water was being hauled large distances.

These factors provided the impetus for the development of bulk slurry mix trucks. Fig. 2 shows a Canadian Industries Ltd. Gelmaster slurry truck.

Consideration of the solubility curve vs. temperature for AN clearly shows that by going to elevated temperatures all of the AN can be put into solution using the 15% water that the formula requires, and this then acts as the vehicle to carry the AN in the slurry mix truck.

For many mixes, the liquor is often partially pregelled. This has the advantage of putting a substantial quantity of air bubbles into the liquor. With NCN mixes the problem is to hold air bubbles on the aluminum surface. Premixing of the aluminum and other fuels by some producers enables

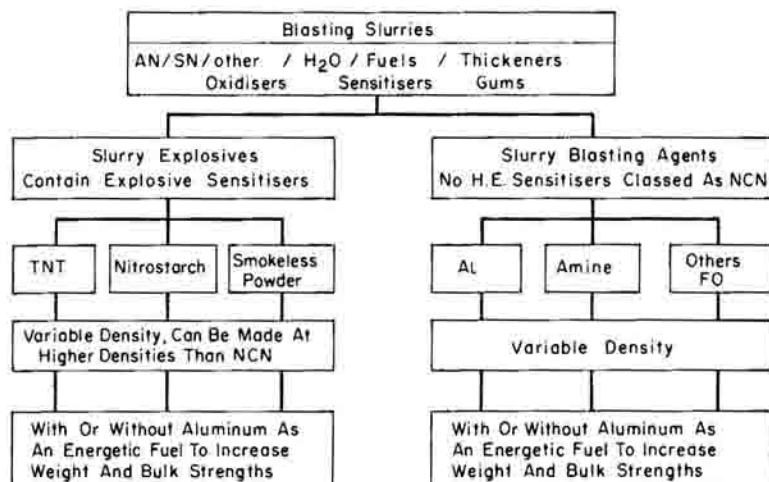

Fig. 1. Classes of blasting slurries.

this to be done properly. Others do it by *Slurrexing*, by adding gassing agents to the mixture. *Bicarbonate* produces carbon dioxide. The quantity is varied to vary the density.

Compositions based on aluminum or air bubble sensitization have critical densities beyond which they will not shoot. These are considerably lower than HE sensitized slurries and have to be controlled carefully. In wet holes, pumping air can cause problems and so can pumping a low density slurry. Many densities in the hole are 1.2 to 1.3 g/cm³ and pumping density is usually lower than this at approximately 1.1 g/cm³.

Truck pumping rates are variable with the larger units now being able to deliver at 700 kg/min (1500 lb per min). Weightometers are commonly fitted to the bins, offering the opportunity to automate the explosive delivery record keeping. This facility, along with automatic drill recording units, has spurred the introduction of computer programs designed to give complete control of the drilling and blasting costing and evaluation.

Slurries

Although fuel oil/gas bubble sensitized water gels are still very popular and relatively cheap, they do suffer from the following disadvantages. First, because they are gas bubble sensitized, they are subjected to desensitization under hydrostatic heads. This is overcome to some degree by adding

aluminum to the basic slurry or by incorporating additional gas into the product. For wet hole application, the minimum fully gassed density that can be employed is 0.95 g/cm³. With loading beneath water and with a slurry column above the end of the hose, the hydrostatic head on the slurry is sufficient to bring the slurry density to greater than 1.05 g/cm³ and thereby avoid floating. However the critical density of the basic fuel gas bubble slurry is approximately 1.15 g/cm³ for a 200-mm (8-in.) critical diameter. This means the maximum hydrostatic head in a wet borehole that can be tolerated for this critical diameter is 0.1-MPa (14-psi) overpressure. For dry holes this is not such a problem since the slurry can be gassed down to densities much lower than 0.95 g/cm³, so that under the existing hydrostatic head conditions it will not be precompressed beyond its critical density.

Fig. 3 shows the effect of density on the critical diameter and the detonability limits of a typical air bubble fuel oil slurry containing different percentages of aluminum. Because of the cost of aluminum and the large amounts needed in deep holes such as encountered in dragline stripping operations, if the extra energy is not really required, there has been a trend to mechanical means of sensitization for lower cost. This can be achieved by the use of microballoons or the use of solid void-filled ingredients in the compositions.

The microballoons in combination with a lower aluminum content permit retention of the sensitivity at lower cost than the high aluminum content mixes.

Table 1 shows the critical density and maximum hydrostatic heads that chemically gassed compositions can be used under in wet holes. For comparison purposes TNT-based slurries are included. Some of the amine-sensitized slurries have similar properties to the TNT ones, but they also suffer from the disadvantages of higher cost than the low grade fuel oil slurries. Other slurries are sensitized using methylamine nitrate and ethylene glycol mononitrate. The shelf life difference between the two classes of slurry in Table 1 is also noteworthy and clearly the use of the low grade fuel oil slurries in wet holes is limited to a short in-hole exposure time.

Emulsions

Because of the foregoing, blasting emulsions, in which the oxidizer is dispersed throughout the continuous fuel oil emulsion phase, are receiving increasing attention.

The manufacture of blasting agent emulsion is usually performed using an ammonium nitrate water solution or a

Fig. 2. Gelmaster slurry truck.

Fig. 3. Effect of density on the critical diameter of aluminized air bubble slurries containing different percentages of aluminum.

calcium nitrate, ammonium nitrate water solution emulsified in fuel oil using 1 to 2% of a suitable emulsifier such as sodium oleate or sodium stearate. The calcium nitrate is sometimes used to replace some 50% of the ammonium nitrate to help reduce cost, although the calcium produces solid oxides as a product of detonation so that useful energy output is somewhat reduced. Other salts sometimes used include sodium nitrate, to perhaps 33%, to reduce solution temperature and early mixes used ammonium perchlorate to improve sensitivity. The water content in the solution varies in the 14 to 20% range and solution temperatures range from 60 to 70° C, depending on the salts used. The fuel oil content is commonly approximately 4% but varies to produce the correct oxygen balance. For consistency, varying amounts of wax may also be employed as part of the fuel and to improve shelf life. For a field mix system perhaps 1% wax would be employed.

As with the NCN slurry system, aluminum may be added to increase the weight and bulk strengths of the emulsion as well as to improve the sensitivity. In North America some manufacturers incorporate 1 to 2% glass microballoons in all of their emulsions to ensure sensitivity and to help control

density. Microballoons would be added if the emulsion were to be used by itself or if added to ANFO to make heavy ANFO. The cost of the microballoons is approximately twice that of aluminum and so a 1.5% addition produces an emulsion of cost similar to a 3% Al fuel oil bubble sensitized slurry.

While emulsions have good water resistance to standing water, they do not have good resistance to water jetting into the borehole since they do not have the physical strength of a gel.

Blasting emulsions have very flat velocity of detonation charge diameter curves. They rise rapidly from the critical diameter to the thermohydrodynamic value, in contrast to the non-high explosive slurries which have a much more gradual rise associated with them. This probably is a reflection of a more intimate degree of mixing. With the significantly higher detonation velocities at intermediate diameters of charge 75 to 175 mm (3 to 7 in.), it would appear that the emulsion products would have a possible performance edge in this size range.

Emulsions can be gassed in a similar manner to the NCN slurries and sometimes microballoons are added to help con-

Table 1. Critical Densities, Hydrostatic Head Limits and Shelf Life for TNT Slurries and Fuel Oil Air Bubble Sensitized Slurries When Used in Wet Holes

Explosive	Critical Density (g/cm ³) For a 150-mm (6-in.) Unconfined Critical Diameter at 5°C	Maximum Hydrostatic Head		Shelf Life Wet Holes

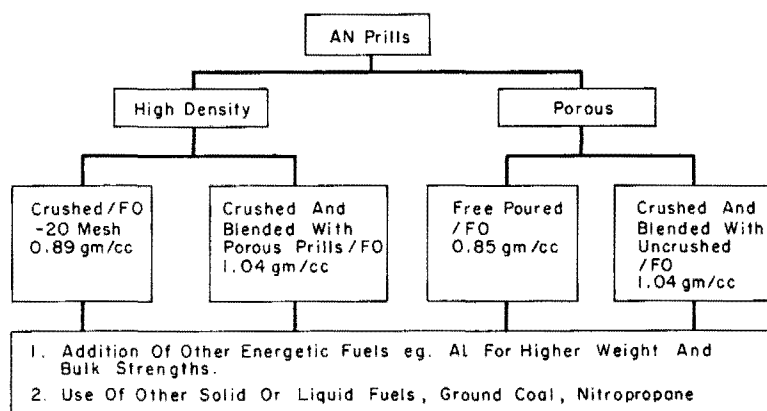

Fig. 4. Classes of ammonium nitrate dry mixes.

trol density in both emulsion and heavy ANFO. High velocities producing high brisance is the result, which can be very beneficial when blasting the higher strength rocks.

Ammonium Nitrate Dry Mixes

Fig. 4 illustrates the classes of ammonium nitrate dry mix explosives.

There are a number of different forms of ammonium nitrate, all of which have been used in explosives at one time or another. The porous prills are most suitable for use with fuel oil directly as a blasting agent. The anti-caking agents usually used are Kieselguhr up to 2 to 3% or surface active agents such as some of the sulfonates, a fraction of 1%, or combinations of the two. Ammonium nitrate is an oxidizer and for each molecule, (NH_4NO_3) , there is an excess of one atom of oxygen.

A variety of fuels could be used with the ammonium nitrate. Fuel oil is cheap and easy to apply. For maximum energy output, the oxygen balanced mix of approximately 94.4% AN to 5.6% FO gives the optimum mix.

The energy output can be calculated for different ratios of ANFO. Maximum energy output occurs when the excess oxygen is used by the fuel to give only carbon dioxide, steam, and nitrogen. This is called the zero oxygen balanced mixture. If the nitrogen combines with oxygen, as occurs in an

underfueled mix, an endothermic reaction occurs producing nitrogen oxide, reducing energy output. Further underfueling or mixing with air produces the telltale brown fumes of nitrogen dioxide. Brown fumes from an ANFO blast indicate that either there was insufficient fuel present or the ANFO was attacked by water.

Fig. 5 shows the effect on the energy output of different percentages of fuel oil added to AN. On both sides of the oxygen balanced mixture, there is a fall off in energy output, but it is more pronounced on the fuel lean side. Because of this, most operators run the mixture slightly fuel rich.

Fig. 6 is a schematic of the feeding and mixing arrangement of an ANFO mix truck. Calibration is afforded by interlocking the speed of the AN delivery auger to the back of the truck with the fuel oil pump. In view of the sensitivity of the energy output to variations in fuel oil content, great care must be taken in maintaining accurate calibration. For this reason some operators, notably in Africa and Australia, are now going to the "concrete style" ANFO mix truck concept.

Table 2 presents the specifications for porous prilled ammonium nitrate suitable for the manufacture of ANFO. Porous prills usually hold the fuel oil well but dense prills do

Fig. 5. Energy output vs. percent fuel oil added to ammonium nitrate.

Fig. 6. Schematic of the feeding and mixing arrangement of an ANFO mix truck.

Table 2. Specifications for Porous Prilled Ammonium Nitrate

Oxidizer Specifications:	Less than 0.1% by weight of carbon in the coating. Will not detonate in a 100-mm (4 in.) diam schedule 40 steel pipe when primed with a 4 g primer and fired at 25°C. Will not go to detonation in a burning test.
Size:	General -6+14 mesh (US Sieve), unless for a freeflowing product.
	Typical Size Distribution by Weight:
	- 6 +10 mesh 22.8%
	- 10 +12 mesh 32.0%
	- 12 +14 mesh 32.7%
	- 14 +16 mesh 8.9%
	- 16 +20 mesh 3.4%
	- 20 +35 mesh 0.2%
Coating:	Clay and special parting agents approx. 1.6 to 3% by weight
Density:	Different products have bulk density 0.82 to 0.90 g/cm ³ and should not vary widely for a particular product.
	Some low density products at 0.68 to 0.70 g/cm ³ tend to be too sensitive.
Porosity:	Minimum fuel oil retention 6% by weight, and should retain this indefinitely.
Free Flowing:	
Critical Diameter:	When mixed with 6% by weight of fuel oil and free poured will shoot unconfined in a 125-mm (5-in.) diam cardboard 1 m (3 ft) long when primed with 60 g of pentolite at one end. Should not be cap or fuse sensitive.
Hardness:	Should be such that there will not be excessive prill breakdown in handling or in the normal temperature cycling that can occur during a reasonable time period (2-3 months). This would clog auger, cause caking, etc.

not (less than 2% when mixed). It is necessary to increase the surface area of this form of AN to get adequate FO retention. This can be done by incorporating hammer mills on the back of bulk trucks and, with the correct size of screen, procure a product that has the necessary surface area. As a rule if the dense prills are crushed to 96% -850 μm (-20 mesh), then the fuel oil retention characteristics are as good as porous prills. To do this, a 6-mm (0.25-in.) screen is used and the hammer mill is run at about 1800 rpm. The reason for going to such a system is purely economic in that these AN products are very often significantly lower in cost.

ANFO does, however, suffer from the disadvantage that it has to be used in dry conditions and that in order to utilize on-site bulk mixing and loading, it is necessary to use prills having a rather narrow size distribution so that they flow quite readily. This results in a product having a low density generally in the range of 0.80 to 0.85 g/cm³. The energy output in large diameter holes is approximately 903 cal/g. This means that ANFO, while having good weight strength, has only a moderate bulk strength. Attempts over the years have been made to improve this aspect of ANFO and the approaches taken have been to:

1. Replace part of the fuel oil with more energetic metal fuels such as aluminum or appropriate aluminum alloys.
2. To use blends of sizes of ammonium nitrate to attempt to fill in part of the voids between the prills. Alternatively to use this approach in conjunction with liquid fuel nitro compounds which require a somewhat higher percentage than fuel oil to oxygen balance the ammonium nitrate. This would give some fluidity to the fine ammonium nitrate and ease the void filling operation.
3. To use a blasting emulsion with the appropriate emulsifying agents and to use this to fill or partially fill the voids

between prills, depending upon the level of addition. This is the so-called heavy ANFO. The emulsion in some instances is sensitized with microballoons or other hollow gas containing material. In other cases it is not.

With regard to the addition of energetic fuels to ammonium nitrate and fuel oil, it is well recognized that as aluminum is added, the fuel oil is reduced in order to produce the optimum energy output. The particle size of the aluminum is also selected so that it will be fully reactive in the blasthole size in use. It should also be dust free to avoid the possibility of hazards associated with dust in handling. Table 3 presents the specifications for aluminum granules for dry mixes. The energy output is increased to 1650 cal/g of mixture when aluminum reacts with ammonium nitrate up to an additional level of approximately 18% by weight. However, as opposed to ANFO where the entire products of the detonation reaction are gaseous, solid products of reaction, Al_2O_3 , are now produced. The energy output is therefore partitioned between the gaseous and solid products of re-

Table 3. Specifications for Aluminum Granules for Dry Mixes

Size:	100% -20+150 mesh
Purity:	94% Plus Aluminum Mg Content Not Critical as for Wet Mixes
Dust:	Should be Dust Free for Bulk Mixing Operation
Density:	Should be Consistent for a Bulk Mixing Operation so that Calibration is not Being Changed Continually
Flow:	Should be Free Flowing for a Bulk Truck Application

action. In practice and in test evaluations, half of the energy associated with solid products of reaction cannot be obtained usefully from the system. Evidently this is because during the work process in which the explosive gases are expanding, the solid products of reaction cannot transfer all of their contained heat rapidly enough to do useful work. At the same time, the gas volume per unit weight of explosive also has been reduced as aluminum is added. Despite these shortcomings, there is a significant increase in the energy output as aluminum is added to ANFO. Fig. 7 is a plot of the strength relative to ANFO of Al/ANFO containing various percentages of aluminum. Since the addition of aluminum to ANFO also increases the density slightly, this will influence the relative bulk strength. Table 4 gives the bulk strength compared to ANFO for Al/ANFO containing various percentages of aluminum up to 15% by weight. The optimum formulations for these various percentage aluminum additions are indicated. Fig. 7 indicates that the increase in energy output with aluminum addition is approximately linear up to 7% by weight. After this the incremental increase in energy output with further aluminum addition decreases. For this reason unless the drilling cost is excessive, it is usual to find a maximum addition of aluminum to ANFO of 15% by weight and more commonly a maximum percentage addition of 7 to 10%. For dry hold blasting, the use of Al/ANFO in combination with ANFO is often an economic proposition.

Heavy ANFO

More recently, attempts have been made to densify ANFO using emulsions of ammonium nitrate, calcium nitrate water, and fuel oil with the appropriate emulsifiers to form a water in oil emulsion. Such compositions containing up to 45 to 50% by weight of emulsion are now being used for wet holes. Bulk trucks have been developed to blend the emulsion with AN or ANFO and to auger feed the product through water leads to considerable water inclusion in the column, which seriously reduces the effectiveness of the charge. For holes containing relatively small amounts of water, the shock on impact is sufficient to take the emulsion from the solid ammonium nitrate surface and allow part of the ammonium nitrate to go into solution. Again, this reduces the effectiveness. Blasthole polyethylene liners with slits in the wall are now being used to successfully load heavy ANFO in water-filled holes.

Comparison of Slurries, Emulsions, Heavy ANFO, and Dry Mixes

Fig. 8 shows the effect of the addition of aluminum on the weight strength of ANFO compared with values for typical slurries of both NCN and the TNT sensitized types, emulsions, and heavy ANFO. From this graph, it can be seen that the increase in energy output for each blasting

Fig. 7. Relative weight strength of Al/ANFO containing various percentages of aluminum.

agent is comparable for increased quantities of aluminum addition.

Fig. 9 presents the corresponding blasting agent bulk strengths relative to ANFO for different aluminum additions. Now the advantage of increased loading density becomes apparent. The TNT-sensitized slurry and heavy ANFO give the highest relative bulk strengths closely followed by the bagged TNT-sensitized product, which is slightly lower because of the voids introduced into the loaded explosive column. Heavy ANFO bulk strength does vary depending on the proportion of emulsion to ANFO used and the final loading density. Basic NCN slurry and emulsion have similar strengths if they are manufactured using the same oxidizers and have the same water contents.

Table 5 shows how the weight and bulk strength concepts may be used. Relative powder factors can be obtained from the relative weight strengths by dividing the powder factor for ANFO by the weight-strength relative to ANFO.

Toe pulling capability or collar height is dependent on the action of the ends of the charge. This is approximately hemispherical and is therefore related to the one-third power of the useful energy in the bottom or top part of the charge (approximately eight diameters). For a given fixed diameter of blasthole, the toe pulling ability is proportional to (the bulk strength)^{1/3}. If the toe distance divided by the (bulk

Table 4. Relative Bulk Strength for AL/ANFO

Explosive	Density, g/cm ³	Relative Weight Strength	Relative Bulk Strength (Relative to ANFO at a Density of 0.83 g/cm ³)
ANFO	0.83	1.00	1.00
Al/ANFO 5/90.5/4.5	0.87	1.13	1.18
Al/ANFO 7/89/4.0	0.88	1.18	1.25

Al/ANFO 15/83.6/1.4	0.94	1.35	1.53

Fig. 8. Weight strengths relative to ANFO for Al / ANFO dry mixes and for aluminum and TNT-sensitized slurries and emulsions containing different percentages of aluminum.

strength)^{1/3} is kept constant, then the similar results will be produced.

Collar heights are scaled in a similar manner, the burden is now the depth from the top of the bench to half way down the top eight diameters of charge. If this scaled distance is

Fig. 9. Bulk strengths of dry mixes, emulsions, heavy ANFO, and slurries with different aluminum contents.

Table 5. Relative "Powder Factors" and Toe Pulling Capability for Different Blasting Agents

Explosive	Density, g/cm ³	Weight Strength, ANFO=100	"Powder Factor" Relative to ANFO	Bulk Strength Relative to ANFO at a Density of 0.83 g/cm ³	Toe Pulling Capability Compared to ANFO (Rel. Bulk Strength) ^{1/3}
ANFO	0.83	100	1.00	1.00	1.00

Emulsion, 16% H ₂ O	1.25	77	1.30	1.16	1.05
Heavy ANFO, 50% ANFO, 50% Emulsion	1.35	89	1.16	1.45	1.13
Aluminized Heavy ANFO, 10% Al	1.37	114	0.91	1.88	1.23

kept constant, then similar results will be produced at the top of the bench.

Explosives Selection Factors

The factors that go into the selection procedure are as follows:

1. Critical diameter and the factors that affect it, such as hydrostatic pressure and temperature.
2. Minimum primer weight and the factors which affect it.
3. Density.
4. Weight strength.
5. Bulk strength.
6. Gap sensitivity.
7. Water resistance, loading procedures, gelling rates, etc.
8. Coupling or decoupled properties if used for wall control work.
9. Shelf life.
10. Sensitivity primacord downlines.
11. Reliability and quality control for bulk operations.
12. Overall drilling and blasting economics.

Careful observation indicates that blasting results can be correlated with the total energy input per ton of rock, providing there is adequate subgrade, bottom charge, stemming, delays, etc. The most important characteristics of explosives for blasting are their useful energy outputs per unit weight and per unit volume, that is, their weight and bulk strengths. Typical values have been presented in Table 5.

PRIMING AND INITIATION SYSTEMS

The onset of detonation is without doubt thermal in origin and since reaction rates are exponential functions of temperature, then those explosives that generate the highest pressures at the primer-explosive interface will be the most efficient primers, in other words, those explosives having the highest detonation pressure. The considerable work by Cook, et al. (1968), shown in Fig. 10, clearly demonstrates that the size or weight of the primer necessary to prime ANFO or blasting slurries is a function of the detonation pressure of the primer. Those primers having high detonation pressure such as cast pentolite (detonation pressure 210 kbars) require relatively small weights compared to the less efficient lower detonation slurry primers (detonation pressures 110 kbars

or less). Because of this, it has been usual to use high pressure cast primers for priming of blasting agents. Weights usually used are from four to six times the minimum primer weight, determined at an unconfined charge diameter of somewhat greater size than the critical diameter of the explosive to be primed.

Fig. 11 shows typical priming test results for crushed high density prills/FO in steel pipe. It shows a minimum primer weight of 105 g (0.23 lb) of pentolite. For large diameter blastholes, 450 g (1 lb) primers are adequate.

Slurries for large diameter blasthole application under normal conditions have minimum primer weights of approximately 80 to 100 g (0.18 to 0.22 lb). One pound primers once again are adequate. With NCN slurries the minimum primer weight is strongly dependent on the temperature of the slurry. If it is hot then it can become cap sensitive.

Emulsions and heavy ANFO have similar priming requirements to regular ANFO and slurries. For most blasting 450-g (1-lb) cast pentolite or procure primers are standard.

The predominant method of priming, which is easy to do, as well as being extremely safe, is to use detonating fuse downlines to the cast primers from the surface primacord truck lines with nonelectric detonating delays between holes. In some parts of the world, there has been trouble with misfires due to poor tensile strength and PETN packing in the core of the detonating fuse. Heavier blasting to produce better top fragmentation shows up these deficiencies and, in hard rock blasting with relatively short collars, it is necessary to use high quality detonating fuse downlines. Surface trunk lines can be of lower quality, 10 g/m (40 grains per ft) and lower tensile strength. Downlines are tied to the trunk lines. Care should be taken with primacord angles to ensure they are as near right angles as possible.

In areas subject to massive ground motion along contacts, which can cause cutoffs close to the collars of the holes prior to their firing in the normal sequence, use is being made of nonelectric down-the-hole delays such as the toe-det system developed by Canadian Industries Ltd. A standard long delay (100-125 msec) on a low energy detonating cord (LEDC) is put down each hole. LEDC is used so that the primer, into which the delay is placed, will not be shot ahead of the delay by the detonating cord. The blast is then tied up in the normal manner using a normal surface delay sequence.

Fig. 10. Minimum booster weight as a function of booster detonation pressure (Cook, 1968).

Fig. 11. Velocity run-up distances for -20 mesh crushed dense prills/FO fired in 75-mm (3-in.) diam pipes with different booster weights.

The effect of this on firing is to have several rows of surface detonating cord and downlines detonated before the first row of holes start to fire. Alternatively different delay numbers could be used in subsequent rows of holes in the blast, but this does not give any flexibility in the tie up. If the face is not dug out prior to loading the blast, this can give difficulty.

Other nonelectric delay systems include the Deckmaster produced by Atlas Powder Co. This unit uses a regular downline and has the facility to utilize any of a number of different delays between the downline and the primer.

The shock tube system, commonly called Nonel, is proving very successful. These units consist of plastic tubes containing a very light coating of explosive adhering to the inside. The detonation is of such low energy that the tube is not broken during firing. Because of the low activation energy, delays manufactured using Nonel are potentially much more accurate than cordline systems. Other advantages include virtually no blast noise and relative safety as Nonel is not susceptible to stray electric currents, etc. Surface delaying is common using Nonel. Down-the-hole use requires special tubing for explosives loaded at high temperatures such as slurries and emulsion; sleep times should not be long in dry mixes to guard against deterioration of the tube as a result of contact with fuel oil.

Gas systems have had limited use. While they offer some of the advantages of the Nonel system, they are more difficult and less flexible to use.

Electric blasting is still employed by some mines. The low noise and relatively accurate delay afforded by electric blasting caps is essentially duplicated in the safer and more flexible Nonel system. Safety aspects and easier hookup requirements have prompted the development of the Magnedet system. Also the use of sequential blasting machines has expanded the number of charges that may be delay initiated in a single blast. However electric systems currently provide only a small proportion of surface blast initiation.

BLAST PATTERN AND DELAY SELECTION

Fig. 12 indicates what happens when a cylindrical charge is fired in a borehole. As the detonation wave travels up the explosive column from the primer, a high pressure stress

Fig. 12. Section through the face when the charge detonates.

wave travels out into the rock mass. Fig. 12 indicates the position of the detonation front and the stress wave at different time intervals. For a bottom primed charge, the stress wave envelope is pear shaped. Close to the charge, the rock fails in compression due to the high borehole pressures produced and beyond this tensile fractures are produced due to the transverse hoop stress. Fig. 13 is a horizontal section through the charged borehole. It indicates a pulverized zone close to the charge with tensile radial fractures proceeding

Fractures Opened Up And Propagated By Gas Expansion Producing An Isolated Fragmented Rock Mass Or Crater.

Fig. 13. Sequence of events occurring in a horizontal section of the rock mass surrounding a borehole in which a charge is fired.

beyond this. These are caused by the expanding compressive wave trying to tear the rock apart. Fig. 13 shows three successive positions of the expanding compressive wave front at different times indicated by A, B, and C, with the radial cracking proceeding behind the compressive front at a slower speed. At a free face the radial expanding compressive wave is reflected as a tensile wave and travels back towards the borehole causing a series of reflected wave tensile failures. This occurs in massive brittle rocks and, if the reflected tensile failures or slabs meet up with the subsurface failures, an isolated fragmented rock mass or crater is produced. In most bench blasts, however, the rock formations have been blasted over on the previous lift, resulting in inherent fractures being opened up to the degree that the surface reflected tensile failure is minimal and the bulk of the failure proceeds from the borehole outwards. As the radial compressive wave proceeds outwards, it produces tensile failure at right angles to it. Since the wave decays as it travels outward, this occurs close to the borehole where the tangential stress is high enough. The high pressure gases originating at the borehole wall rush into these cracks and attempt to wedge them open. If the burden on the charge is such that the compressive wave is still strong enough to produce tensile failure when it reaches the face, then failure will occur throughout the burden, and as the rock is unloaded due to the reflection of the compressive wave, it is now possible for the expanding gases to wedge open the cracks and start to expel the rock mass. In opening up the cracks, wedging action takes place, and considerably more fracturing results because of this. Since the gases have to sense the release of load prior to any appreciable wedging occurring, then the fracturing behind the charge will be less than in front of the charge; additionally, they will be tight.

For a given material type and explosive charge per unit length of hole, there is a maximum size of burden that can be used and still produce a full crater. Fig. 14 is a schematic illustration of the effect of varying the burden on a constant charge in the same formation. This is a horizontal section through the borehole to the face. In blasting rock it is desirable to detach the burden and produce a full crater. An optimum crater condition is produced in which the rock is completely isolated back to the charge. At depths deeper than this, a shelf of unbroken material remains between the

charge and the free face. For a multiple hole shot, it is possible that this material could be isolated by poor fragmentation. At shallower depths than optimum, the crater is reduced in depth, increased in radius, volume is reduced, fragmentation is finer, the crater assumes more of a bowl than a trumpet shape, and flyrock and noise start to become appreciable. The sequence of events is the same for craters from both spherical as well as off the sides of cylindrical charges. For craters from spheres in brittle rocks, the optimum true crater occurs often at scaled depths of burial, $d/W^{1/3}$ equal to 0.8 m/kg^{1/3} or 2.0 ft/lb^{1/3}, approximately. The factor, $d/W^{1/3}$, is defined as the distance from the rock surface to the charge center (d), divided by the charge weight (W). The contained depth is at a scaled distance of 1.6 m/kg^{1/3} or 4.0 ft/lb^{1/3}.

As the material gets softer, the optimum scaled depth increases. Fig. 15 shows the scaled crater depth vs. scaled depth of burial curve for craters produced off the sides of cylindrical charges fired in massive quartzite. The scaled optimum depth is in the range of 1.2 to 1.45 m/kg^{1/2} (2.7 to 3.2 ft/lb^{1/2}) and containment occurs at a scaled depth in the range of 2.25 to 2.7 m/kg^{1/2} (5.0 to 6.0 ft/lb^{1/2}). Scaled depth in this instance is the depth to the center of the charge divided by the half power of the explosive weight per unit length of hole. For softer rocks the optimum would move to increased values of scaled depth. By way of interest, frozen materials have curves that go from optimum crater sizes to no crater much more rapidly than a brittle rock. The optima are similar.

From Fig. 16 it can be seen that the scaled optimum crater radius occurs at a scaled depth of burial which is close to that for the optimum in depth. Fig. 17 has the same data plotted so that the change in the crater radius depth ratio can be seen. At the optimum crater condition this has an average value in this formation of approximately 0.75. However, as the burden is reduced, this continues to increase. For this reason in hard rocks there is considerable advantage in shooting blasts en echelon if they are laid out in a square pattern or along the long axis if the pattern is staggered. This produces a reduced burden, more displacement, and better fragmentation. There does not appear to be any advantage in going to spacing to burden ratios greater than those encountered with such blasts. Such schemes would lead to more complicated blasthole layouts and, if laid out in a row by

Fig. 14. Schematic of the effect of decreasing the burden on charges fired in rock.

Fig. 15. Change in crater depth produced by different burdens on cylindrical charges fired in quartzite.

row manner, the excessive hole spacing along the front of the blast would make for difficulties, also along the back and sides. This then calls for a considerable amount of extra drilling if the tonnage per blasthole is the same with just changes being produced in the burden to spacing ratio. The en echelon firing has the advantage of keeping the blast more confined along the front, causing less scatter of the muckpile. With 250-mm (9 $\frac{1}{8}$ -in.) holes on a 7.6 \times 7.6-m (25 \times 25-ft) pattern and an explosive loading of 60 kg/m (40 lb per ft) of hole, the scaled burden for the body of the charge would be 1.6 m/kg $^{1/2}$ (3.6 ft/lb $^{1/2}$) if fired en echelon. The curves indicate a noticeable difference in result and this is seen in practice. In soft materials the difference is not as pronounced.

In order for the crater to be produced and for the material to start to be affected, there is a necessary lapse time. If subsequent delay periods are fired prior to this occurring, then the shot starts to become choked. The pit floor conditions fall off, the muck is tight, and in many instances an inadequate delay time interval will result in a significant increase in flyrock from the top of the blast and back throw behind the blast. For some years this minimum delay time

had been receiving considerable attention by Chung, et al. (1975). In the absence of an adequate theory, they began photographing using a dual camera system, numerous blasts to observe the time at which face motion started in bench blasting and also the time and velocity with which the top of the bench started to move. It will be seen that framing rates of the order of several hundred per second are adequate for this work. Fig. 18 shows a plot of a bench face profile from such movies and Fig. 19 a distance time plot for different burdens. Note the time lags before any motion starts to take place. In Fig. 20 similar data are plotted for small diameter blastholes and therefore small burdens. The interesting outcome of this is shown in a plot of time before the face starts to move vs. the burden for holes of different size, Fig. 21. This indicates that the minimum delay time for burden detachment in rock should be no less than 3 millisec/m (1 millisec/ft) of burden. In many instances, there is an advantage in extending the delay period to greater values to produce better lateral relief. These conclusions are in agreement with rules of thumb that have generally been employed.

The upper limit to the delay time that can be used is imposed by the possibility of cutoff holes. Factors influencing

Fig. 16. Change in crater radius produced by different burdens on cylindrical charges fired in quartzite.

Fig. 17. Effect produced on the crater radius/burden ratio with different burdens on cylindrical charges fired in quartzite.

this are the collars on the holes, the spacing of the holes, the charge per unit length of hole, and the material type. Once again, high-speed photography can be used to determine the time delay that occurs in blasting before there is appreciable port movement. Fig. 22 shows typical field data. From these movies, it is also apparent that one can consider the top eight diameters of the cylindrical charge to act like a sphere located four diameters down from the collar. In Fig. 23, the delay time before the top of the shot starts to move is plotted vs. scaled depth of burial of the equivalent spherical charge in rock. One can use this to determine what the scaled distance is from the collar of the hole on the next delay period to see if the maximum permitted delay time is greater than that required to produce the separation. If not, the collar or initiation system has to be adjusted.

Other methods used to determine the maximum permitted delay interval are concerned with the particle velocity generated at the collar of the next row of holes and the amount of elongation that detonating cord can take prior to its failure. This requires assumptions in the length of downline which is stretched, since if one assumes that a 4%

Fig. 18. Profiles seen with high-speed cameras used in the determination of required delay times.

Fig. 19. Burden movement in large-hole blasting 250 mm (9 7/8 in.) in hard rock.

Fig. 20. Burden movement in small-hole, 32 mm (1 1/4 in.) blasting.

Fig. 21. Onset of movement for burdens of different size.

Fig. 22. Top movement in large-hole blasting, 250 mm (9 7/8 in.) using high density slurry.

elongation can be permitted prior to it failing, then in a 15-m (50-ft) hole this could amount to 0.6 m (2 ft). If the surface velocity is such that the detonating cord is not stretched this amount during the delay interval, then the design would be satisfactory. However, if the detonating cord downline happened to be frozen securely into the stemming the extension prior to failure would be very much less.

The other important aspect in the design for pit blasts is the subgrade. This part of the blast scales in the same manner as the collar. For example, in hard rock in going from 250-mm (9 7/8-in.) diam blastholes to 281 mm (15 in.) using the same explosive, then the burden that could be pulled would be $(250/381)^{2/3}$ or $(9 \frac{7}{8}/15)^{2/3}$ or 1.31 times the burden on the smaller hole.

EXPLOSIVE CONSUMPTION

In recent years attempts have been made to model blast designs, in some cases right from first principles. The authors of some of these models have made great claims to their capability and in some instances they have even decried the

Fig. 23. Delay time prior to bench top motion.

common present day approach of the blasting engineer who uses energy factors in his blast design. The assumptions that have to be made when designing these models from first principles in reality negates the claims made. For example when studying the response of a rock mass to an applied stimulus, it is essential to know the applied pressure time history in the borehole. For the same explosive this varies widely. A blasting agent such as ANFO when fired at close to its critical diameter has a velocity of detonation of approximately one-half of its theoretical or *ideal* value which would be the velocity produced in a large diameter borehole. This means that the peak pressure in the borehole will be only one-fourth of the theoretical. It also means that only one-fourth of these explosives have reacted in the determination wave with the balance of the reaction occurring in the expansion phase outside the detonation wave and the rate of reaction will be modified by the interaction with the borehole wall. It is therefore possible that the same explosive can produce a wide range of pressure time impacts. This in turn will produce a wide variation in hoop stress around the borehole which will influence the degree and content of the radial cracking. Models built from first principles have ignored the explosive property variability. The next difficulty with the models that are claimed to produce fragment size distributions is that of the number of cracks in the major fracture sets (one such set would be those radiating from the borehole wall), their orientation, and extent. Difficulties will obviously arise if the assumption is made that the material is homogeneous and isotropic.

One way out of this difficulty is to use an empirical type of approach in which size distributions are determined in the field using photographic methods or photographic examples of known size distributions as a comparison base. Providing all of the important items such as the geometric, geological, delay time and sequencing, operational control,

Fig. 24. Size distributions from blasting and crushing operations.

Fig. 25. Energy-size plot of the data from Fig. 24.

etc., are observed in the blasting operation, then the resulting size distribution of the muck can be related to the energy input.

Fig. 24 is a plot of the product size vs. cumulative weight percent finer than. The results are compared to those of typical crushing operations. The similarity of shape and slope is readily apparent.

Fig. 25 is a plot of the 80% passing size vs. energy input for blasting operations. The dotted line in Fig. 25 defines the relationship between the energy input and the 80% passing product size, and can be determined for this portion of the line from

$$E = \frac{A}{K^{1/2}}$$

where E is the energy input in lbs ANFO or equivalent ANFO per ton of rock, K is the 80% passing fragment size, A is the blasting work index, and $K_1/K_2 = \{E_2/E_1\}^2$ in the same material.

The ratio of the 80% passing size is equal to the reciprocal of the energy input/ton squared.

The use of the 80% passing size is typical of crushing operations. For blasting operations, it is necessary to use a much higher percentage than this, particularly as it refers to the undersized material in a large tonnage operation. Fig. 26 shows some of the difficulty with this in that the curve at the high percentages in many cases is nonlinear. It also indicates the difficulty in interpolating close to 100%. Nevertheless, curves such as these do provide useful information and an estimate can be made of the 100% passing size for a given explosive consumption. This can be used with the preceding equation to estimate the 100% passing size at any other energy input. This has been plotted for sandstone and also for a soft siltstone in Fig. 27, which is a plot of the maximum fragment size vs. explosive consumption. By picking off the fragment size and its corresponding explosive consumption from the curve, the energy required to produce any other size can be calculated. The results from this approach are not perfect but are reasonable if it is recognized that chunks can be obtained off the face, sides, and back of a blast. It can be a good and valuable guide.

Cunningham (1982, 1983) has shown that other size distribution relationships can be used with success to predict or modify size distributions produced by blasting. To do this they have made use of the Rosin-Rammler and Kuznetsov (1973) equations in the development of their KUZ-RAM model for predicting size distributions.

As illustrations of the types of geological effect on fragmentation, Fig. 28 is a sketch of a horizontal slice from the charged borehole to the rock face. In case 1, the charging and burden are such that a full crater would be produced. The rock structure is such that it has no influence on the crater. In case 2, there is a parallel set of fractures running at a small angle to the direction of blasting. The resulting crater is influenced by this because of the energy being reflected by these planes thereby being trapped in a narrow region. The crater which is produced is reduced in radius and the burden that can be broken out fully right back to

Fig. 26. Estimated size distribution from a sandstone blasting operation.

Fig. 27. Fragment size vs. explosive consumption for a sandstone and siltstone.

the charge can be increased slightly. In case 3, the predominant rock fracturing is at right angles to the direction of blasting and this makes for difficulty in hard rocks with wide fracture spacing. The fracture planes reflect the energy and make it more difficult to blast in this direction. The burden has to be reduced. If the same burden is used as in case 1, then it will not be fully detached and there will be sections of unblasted material. In case 5, if a horizontal section is run through the borehole, the blasting to the left or down dip will be difficult and similar to case 4. The difficulty can

be enhanced by the fact that backbreak can produce a large toe burden particularly if the dip is 35° to 50°. Blasting to the right or up dip will not be quite as difficult since with a vertical blasthole the toe burden will not be as large. The easier direction to blast is along strike.

Geology, then, is a very important factor in the blast design and can greatly influence explosive consumption and resulting fragmentation.

SPECIALIZED BLASTING TECHNIQUES

There are many blasting situations which require specialized design techniques, a few of which will be discussed in this section.

Presplitting

Fig. 29 illustrates typical presplit blast layout using 102-mm (4-in) diam presplit holes for 250-mm (9 $\frac{1}{8}$ -in) diam production holes.

For this type of blast, presplit holes would normally be drilled first, ahead of main production holes. The choice can then be made between loading and firing the presplit line or infilling the main blast. In the latter case, the presplit line would be fired instantaneously 100 to 150 millsec before the main blast. As shown in the figure, the presplit line is formed ahead of the main blast and allows the gas being driven back from the buffer row through the radial cracks to terminate at the presplit line.

The presplit row in Fig. 29 has a spacing of 2 m for a 102-mm (4-in.) diam hole and is inclined at 15° to the vertical. The presplit angle is somewhat dictated by rock structure although a slight angle is preferred regardless of structure for long-term stability as well as for best initial results with large production holes.

The figure illustrates the upper bench where two benches will finally run together to form the final face between berms. Presplit drill requirements become clear when presplit holes needed for the next bench are considered. The drill must be capable of drilling close to the previously produced bench face at an angle of 15° beneath itself so the face can be continued to depth. Currently, this means some form of drifter drill is required limiting the hole size to 102 to 127 mm (4 to 5 in.) diam.

The back row of the main production blast, termed the buffer row, must also be carefully designed with respect to standoff distance from the presplit row and spacing as well

Fig. 28. Illustrations of the effect of rock structure on crater formation.

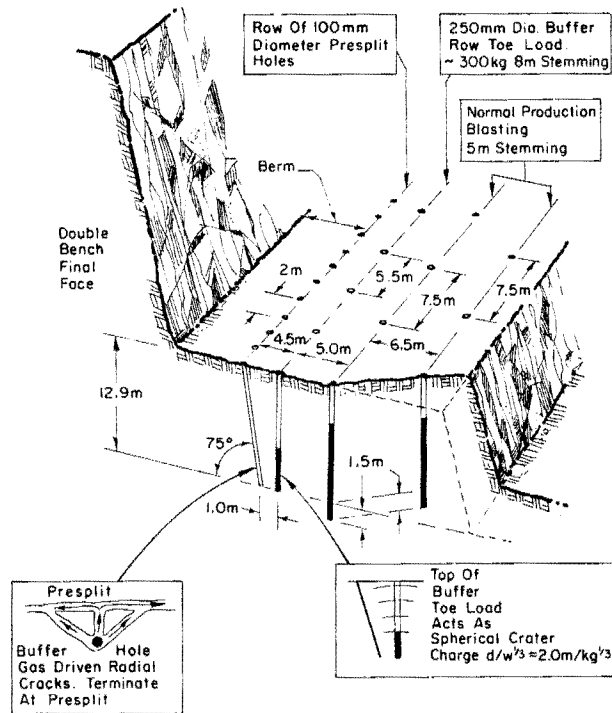

Fig. 29. Presplit blast coupled to a 250-mm (9 7/8-in.) diam production blast.

as explosives load. The inset sketch on the right side of Fig. 29 shows how the top portion of the buffer row hole charge acts as a spherical crater charge breaking to the bench surface. Subsequently, main blastholes after the buffer row are designed at regular spacing, burden, and loading for the type of material blasted.

One further point to note from Fig. 29 is the subgrade or, more accurately, lack of subgrade used on the presplit and buffer row holes. This is to prevent damage to the bench below or to the wall at that point.

Fig. 30 is a graph of recommended hold spacings used in presplitting as a function of hole diameter. These data cover various types of material, but are not fully specified in the open literature.

According to the *Pit Slope Manual* (1977), hole spacing is defined as:

$$S = \frac{\phi (P_w + T)}{T}$$

where ϕ is hole diameter, P_w is pressure at the borehole wall, and T is rock tensile strength.

For a decoupling ratio producing a constant borehole wall pressure in a given rock type, hole spacing is proportional to the blasthole diameter.

Line of constant spacing/hole diameter, ranging from 8:1 to 14:1, have been included in Fig. 30. Generally, published references also show a linear relationship between hole diameter and hole spacing.

Fig. 30. Published relationships between hole diameter and spacing for presplitting.

From the spacing equation, if pressure at the borehole wall is made equal to the dynamic compressive strength of the rock mass, then the spacing must be less than or equal to the ratio of the rock's compressive-to-tensile strength plus 1. For many strong rocks, this ratio ranges from 12 to 15:1.

The first requirement for presplit line loading is adequate decoupling in presplit holes to eliminate crushing. An air-space around a charge is the best way of achieving this. The explosive gases expand out from the charge adiabatically, and the factor of reduced pressure can be expressed as the ratio of the charge diameter to the hole diameter to the 2.6 power, being twice the ratio of the specific heats of the explosive gases, about 1.3. The pressure in bars at the side of the explosive charge can be calculated from the velocity of detonation, D in m/s and the charge density, in g/cm³, by the following equation:

$$P_{\text{side charge}} = \frac{(0.00987) \rho D^2}{8}$$

and the pressure at the wall of the borehole in bars is then:

$$(0.00987) \rho \frac{D^2}{8} \left[\frac{(\phi c)}{(\phi h)} \right]^{2.6}$$

where ϕc is charge diameter and ϕh is hole diameter.

Fig. 31 is a graph of the charge weights per unit length of borehole vs. the presplit hole diameter from various pub-

lished sources, and covers a range of rock types. Higher explosives loading refers to stronger rock types. This graph also includes loading from trim blasting at one large copper producer.

To minimize cratering from the top of the presplit charges, the collar should be such as to avoid cratering. In massive brittle rock, the scaled burial depth of the top eight charge diameters should be 4.0 or greater. In softer formations, it can be as high as 5.0.

The buffer row is the row of holes ahead of the presplit line. When the buffer row is designed, it is essential that the top of the charge is contained to such a degree that it will not crater at the top beyond the presplit line which is fired first.

The presplit line is fired either prior to drilling the main blast or 100 to 150 millisecc ahead of the production rows.

Trim Blasting

Trim blasting is a design technique to give wall control using large diameter rotary blastholes for both production and final row holes. The idea, then, is to eliminate costly small diameter blasthole work, along with the associated hole loading difficulties.

Fig. 32 schematically presents a crest trim and wall trim blast. The upper blast, called the crest trim blast, takes the upper bench to limit. From Fig. 32 the majority of backbreak occurs at the bench crest mostly from previous subgrade. The blast has three distinct components, similar to the presplit blast. A trim row is used to produce the final wall in

Fig. 31. Published charge weight per unit length of borehole for wall blasting.

Fig. 32. Crest and wall trim blast using 250-mm (9 $\frac{7}{8}$ -in.) diam holes in hard brittle rock.

a similar manner to the presplit row. The trim row is decoupled as shown in Fig. 31. If stemming is used, then the decoupling calculation is performed using 40% to 50% voids. Again, a buffer row is designed as the last row of the main blast, with increased stemming to prevent cratering back at the surface through the trim row. Normally, two other regular rows of holes would be used in front of the buffer row to complete the trim blast. These two rows would be at normal spacing and burden and would be loaded using the standard procedure for the appropriate material type. All holes would be vertical and would be of production size. For example, in the case of Fig. 32, holes are 250 mm (9 $\frac{7}{8}$ -in.) diam.

Fig. 33 is a graph of hole spacing used in trim blasting as a function of hole diameter from literature references. Spacing generally ranges from 12 to 16 times the hole diameter. These values correspond to a range of rock hardness

Fig. 33. Relationships between hole diameter and hole spacing for trim blasting.

from hard to moderately soft and are for adequately decoupled charges.

The second bench blast used to complete the two bench face, termed the wall trim blast in Fig. 32, is shown on the lower portion of the figure. The blast is similar to the crest trim blast, except the trim row is now 3 m (10 ft) from the toe position. This distance is dictated by drilling equipment size. Some backbreak from the wall trim blast makes the final wall almost continuous, with a slight ripple remaining where the two benches join. It should be noted that this trim blasting technique does not prove effective where the rock structure dips at a shallow angle into the pit.

Presplitting and Casting in Dragline Operations

Fig. 34 illustrates the relationship between drilling and blasting costs, dragline productivity and overall unit costs. A number of mines are now attempting to achieve minimum overall cost by adjusting their drilling and blasting cost to the optimum. In many cases the optimization includes pre-

Fig. 34. Overall unit cost vs. dragline productivity projection for different blasting costs.

Fig. 35. Dragline digging a throw blast in a two-seam coal operation.

splitting and throw blasting. Fig. 35 shows one of the pioneering mines in this regard using BE 1570W size of draglines.

One major reason for presplitting, apart from improved safety, occurs at operations with water problems. The presplit commonly dewateres the blastholes, which enables easy use of dry mix explosives rather than the more expensive slurries. When presplitting a 50-m (165-ft) wide pit for a 300-m (1000-ft) length, the entire presplit block commonly moves up to 1 m (3 ft) towards the mined cut. Main blastholes drilled after the presplit has been fired are usually dry, even in areas expected to be filled with water after drilling.

The second major reason for presplitting is to enhance the throw blasting technique. Fig. 36 shows the reason.

Fig. 36. Comparison between front row burden with and without a presplit.

A presplit face allows accurate control on the burden for the full length of the front row blastholes, allowing more than 60% of the material to be thrown clear of the coal at some operations.

A good portion of oversize from any blast normally comes from the blast face. Using explosives to throw this oversize well clear of the dragline operation to a new spoil pile area makes an excellent base with good drainage characteristics.

Finally, using the presplit line clearly defines the fragmented material for the dragline operator, who no longer needs to cut a batter for the highwall. At the same time, the coal rib is very accurately defined resulting in much lower coal losses. Some mines have recorded reduced coal losses of up to 90%.

Presplitting in coal operations is somewhat different from normal pits. Horizontal bedding and a very pronounced weakness plane at the coal/overburden interface means that a single charge, fully coupled at the bottom of the presplit hole, is adequate to give excellent results.

The presplit hole spacing for a 250-mm (9 $\frac{1}{8}$ -in.) diam blasthole varies from 3 to 6 m (10 to 20 ft) depending on the material's strength and competency. Highly fractured softer materials require a 3-m (10-ft) spacing, while competent higher strength materials, such as sandstones with compressive strength from 82.7 to 103.4 MPa (10,500 to 15,000 psi) are satisfactorily presplit using a 5- to 6-m spacing.

Presplit holes are drilled into the coal and loaded with 60 kg (130 lb) of explosives (usually slurry in wet conditions). The charge is placed on the hole bottom or suspended just above the bottom by 1 to 1.5 m (3 to 4 ft) using a borehole liner. No stemming is used, and it is preferable to dewater if possible. The presplit row is then fired instantaneously, prior to any main blasthole pattern.

The presplit line is drilled around the complete proposed blast area. The cutoff to the face is made at the blast cutoff angle, which is usually either 45° or 60° with the face. Once an area has been presplit, the entire block of material must then be blasted to avoid poor fragmentation at blast interfaces. This main overburden blast is shot in the normal manner with a 3 to 4 m back row standoff from the presplit line for a 250-mm (9 $\frac{1}{8}$ -in.) diam hole. Fig. 37 presents an overall plan view of the presplit and main blast showing the method of delaying and relative positions of the blasts. If operating and scheduling constraints warrant, the presplit blast may be drilled and fired by itself.

An important control on the quantity of throw is the blast depth/width ratio (McDonald, et al., 1982). Fig. 38

Fig. 37. Plan view of a typical presplit and throw blast tie-in using 250-mm (9 7/8-in.) diam blast-holes.

presents the relationship between percentage blast throw vs. blast depth/width ratio experienced at Rietspruit Opencast Services.

Crater Blasting

Cratering using spherical charges finds wide application in surface mining operations. For example, crater blasting test results are commonly used to design the correct blasthole collars either for fragmentation or flyrock control.

Other more specialized applications include blasting tar sand to prevent frost penetration during winter operations, coyote blasting, and the disruption of planes of weakness in slopes to aid stability.

BLAST VIBRATION AND AIR BLAST

The principal factors that affect vibration levels at a given point of interest are the weight of explosive fired, the distance from the blast, the delay period used, if any, and the blast geometry. The type of explosive, although weight strengths can differ by 40% or more, has not been shown to significantly affect vibration levels other than for very close measurements [6 m (1.8 ft) or less]. Geology does materially

affect levels of vibration, but due to each measuring site being unique, it must be evaluated on a site by site basis.

In general, a scaling factor based on distance is used, being derived from the effects of geometrical dispersion of the outbound ground motion from the explosion. The total energy introduced into the ground by the charge detonation varies directly with the charge weight. The vibration propagates outward from the blast such that the volume of rock subjected to the compressional wave increases. Since the energy in the ground is distributed throughout successively larger volumes of rock, the peak ground motion levels must decrease.

Considering bench or overburden blasts having relatively deep blastholes, the explosive column approximates the shape of a cylinder having a much greater than 6:1 length to diameter ratio. The expanding wave front from charges such as these adopt an expanding cylindrical shape. The volume of this compression cylinder varies as the square of its radius. Thus the peak particle motion at any point from this type of shot will be inversely proportional to the square of the distance from the blast.

The scaled distance, therefore, combines the effects of charge weight (W) on the geometrical dispersion of the vibration at distance (d) in the form $d/W^{1/2}$. An empirical equation of the form

$$V_{\max} = K \left(\frac{d}{W^{1/2}} \right)^m$$

relating the peak particle velocity with scaled distance must therefore be developed. Local site factors for each vibration component, K and m , allow for the influence of geological characteristics on the peak particle velocity and can be determined from a logarithmic plot of peak particle velocity versus scaled distance.

This scaling relationship must be further modified when delayed blasts are to be considered. The explosive weight becomes the explosive weight per delay. This is the total explosive weight fired instantaneously. Delays of 15 millisecond or greater have been found sufficient length to isolate individual detonations.

Vibration Effects

The problem of vibration from blasting is one of the most pressing facing mine operators in populated areas, both from a potential structural damage claim situation and from the standpoint of the annoyance effect on people.

Generally approaches to the problem have been made in two ways. First, attempts have been made to predict vibration

Fig. 38. Relationship between percentage blast throw vs. depth/width ratio experienced at Rietspruit Opencast Services (McDonald, et al., 1982).

levels from blasts and to correlate these with damage, thereby permitting the avoidance of conditions that may lead to damage or annoyance. The second approach has been an investigation of methods whereby blast vibration levels may be reduced.

This in turn has led in many instances to legislation concerning blasting in proximity to nonmine or quarry owned property such as dwellings or plants.

In recent years the question of what constitutes a valid criterion for damage has been discussed by a number of authors. Extensive statistical reviews have been made of published vibration data to determine which of the blast-induced parameters such as particle displacement, velocity, or acceleration best measure the damaging effects of a vibrational wave on a structure.

The current conclusion is that damage can best be correlated with peak particle velocity of the wave regardless of the direction of the motion; longitudinal, vertical, or transverse (Edwards and Northwood, 1960; Langfors, et al., 1958; Nichols, et al., 1971). Because of this, some investigations use the peak resultant particle velocity. It has also been concluded that due to the complex nature of the waves generated during blasting, such as P, S, Rayleigh, Love waves, etc., that it is impossible to correlate damage theoretically with a specific wave form. Because of this, it is usual to lump all of the waves together by measuring the composite wave form and to correlate the results empirically.

Some investigations have given consideration to the frequency response spectra of structures which is sometimes being used. For general application this is not necessary.

Blast Vibration Measurement

In the measurement of vibration, the objective is to detect and record the vibratory motion of the ground. The quantities measured must result in a full description for the vibratory event. This requires three orthogonal components of either particle displacement (x), velocity (v), or acceleration (a), to be recorded as a function of time (t). The three components are termed:

1. Longitudinal, normal to the direction of the blast in the horizontal plane.
2. Transverse, perpendicular to the direction of the blast in the horizontal plane.
3. Vertical, perpendicular to the direction of the blast in the vertical plane.

The basic problem associated with the measurement of blasting vibrations is the establishment of a fixed point in space from which to measure. During the passage of seismic energy, the entire environment is in motion which includes the measurer and the measuring instrument. The seismometer (or vibrograph) overcomes this problem by establishing a reference point within itself that tends to remain fixed during the movement of its housing.

For typical blast vibrations it is necessary that the seismometer should be able to record the following ranges:

Frequency, 1 to 100 Hz.

Displacement, 0.00254 to 12.7 mm.

Velocity, 0.254 to 254 mm/s.

Acceleration, 0.005 to 2 g.

For overburden blasts and other large blasts measured at distances greater than 305 m (1000 ft), the blast frequency is generally in the 1 to 20 Hz range (Attewell and Farmer, 1964). Higher frequencies are experienced closer to the shot point and frequency responses of 500 Hz and more are required for instruments measuring close to blasts in high strength rocks such as granites.

For accurate recording, it is essential that the seismometer maintain fixed contact with the ground or other surface throughout the duration for the vibration passage. If the monitoring head slips in a horizontal direction and/or loses contact in a vertical direction, a useless seismogram will result.

There are three main types of seismometer. One type uses a mechanical optical system. These units measure amplitude and frequency, usually in one component direction only, by direct writing on paper or by light beam on photographic paper.

Electromagnetic systems utilize differential displacement between a moving coil and a soft iron mass (or vice versa) producing an electrical signal output proportional to the seismic event. This unit is referred to as a transducer. The signal so produced is then amplified by a stepped gain setting and fed into a recorder to give velocity. Integrating and differentiating circuits may be included to read displacement or acceleration. Output is usually via a timed, variable speed, direct print paper, the three mutually perpendicular components being measured simultaneously.

Both of the previous systems suffer to some extent from sympathetic resonance of the instrument at certain frequencies. This is overcome using calibration charts. In an attempt to correct minor interpretational difficulties due to resonance, a third type of seismometer has been developed based on solid-state accelerometers feeding into integrating circuits.

Large-Scale Open Pit Blasts

Fig. 39 presents peak particle velocity plotted vs. scaled distance for open pit and rock strip mine multiperiod blasts which contains more than 10,000 data points recorded worldwide (representative data only being shown on the graph itself). As such, Fig. 39 represents a very conservative design criteria when the upper limit line is used for design purposes.

Fig. 39. Typical vibration data from multiperiod delay blasts in open pits and strip mines.

Table 6. Types of Damage Related to the Peak Particle Velocity in the Ground Waves from Blasts

Type of Structure	Type of Damage	Peak Particle Velocity Threshold at Which Damage Starts	
		mm s	in. per sec
Rigidly Mounted Mercury Switches	Trip Out	12.25	0.5
Houses	Plaster Cracking	50	2 Set initial Limit of 125 mm/s (5 in. per sec) Maximum at the Crusher
Concrete Block as in a New House	Cracks in Blocks	200	8
Cased Drill Holes Retaining Walls, Loose Ground Mechanical Equipment Pumps Compressors	Horizontal Offset	375	15
	Shafts Misaligned	1000	40 Beyond 250 mm/s (10 in. per sec) Major Damage Starts, Such as Possible Cracking of Cement Block
Prefabricated Metal Building on Concrete Pads	Cracked Pads Building Twisted and Distorted	1500	60

Table 6 presents the type of damage that can be expected in relation to the threshold values of peak particle velocity experienced in the ground waves from blasts. As can be seen, the onset of plaster cracking in houses occurs at a threshold peak particle velocity value of 50 mm/s (2 in./sec). This is an almost universally accepted damage control criteria in North America. In Fig. 40, the peak particle velocity damage threshold values have been superimposed on the upper limit line. In addition, vibration levels for trucks and buses and damage to water wells are shown. This, then, offers a useful guide with regard to safe scaled distances that may be employed.

Human Response to Blast Vibration

Fig. 41 shows the results of the experimental work of Goldman (1948) in which tests were conducted using sinusoidal mechanical vibrations of different frequencies and particle velocity on human test subjects. Since the frequency of pit blasts are often in the range of 10 to 30 cycles per second, then this data can be used to determine the range of scaled distance from the pit blast peak particle velocity upper limitations at which certain human reactions take place. This has been done in Fig. 42 from which it can be seen that blast vibration effects became intolerable to humans at levels appreciably lower than levels at which structural damage takes place. The result is that often complaints can be received due to human response and not due to a situation producing damage, and in these instances a reduction in the peak particle velocity limit to take care of this situation is a good philosophy, particularly if such a change does not produce operational difficulties. Limits used in the US of peak

particle velocity of 12.5 mm/s (0.5 in. per sec) reduce the number of complaints by a factor of three compared to 50 mm/s (2 in. per sec). It has been noted by the USBM that the percentage of people complaining about blast vibration on one construction site was as high as 30% at 50 mm/s (2 in. per sec), 10% at 12.5 mm/s (0.5 in. per sec), and 1% at 2 mm/s (0.08 in. per sec), which is just in the perceptible range. In some instances, therefore, the human response becomes the major element in the blast design.

The current blasting code for Ontario, Canada, calls for a maximum peak particle velocity of 10 mm/s (0.4 in. per sec).

Noise and Air Blast

Whenever a pressure wave travels through the air faster than a sound wave, it produces a shock wave. The airborne pressure wave emanated from an explosion, called air blast, is a shock wave. At first it travels at supersonic speed, but, depending on the magnitude of the energy released by the explosion, it will decay in time to an ordinary sound wave.

Noise or sound is a pressure wave traveling through air at approximately 335 m/s (1100 fps). A sound wave consists of a train of high pressure regions following one another in rapid succession with the frequency of the sound and separated by regions of lower pressure. The frequency of sound varies from approximately 20 to 20,000 Hz, which is the range that can normally be detected by the human ear.

Air blast acts in a similar manner to noise or sound as it is also a pressure-type wave. However, it has a greater speed than that of sound and its frequency is less than 20 Hz, so consequently it cannot be heard. Its effect, though,

Fig. 40. Structural response at different scaled distances from pit blasts.

Fig. 41. Response of the human body to mechanical vibration (Goldman, 1948).

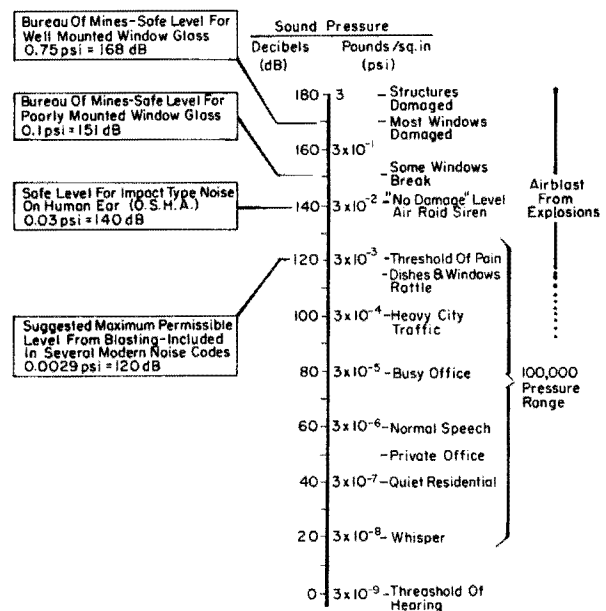

Fig. 43. Human and structural response to sound pressure level.

is apparent in the rattling of windows, etc. The positive phase of the air blast wave is much greater than a sound wave and the following lower pressure region actually changes to a negative value.

To get a feel for the relative sound levels, Fig. 43 presents typical human and structural responses to different scale level.

Air Blast Control

In pit blasting, noise or air blast can be due to any of the following items:

1. Primacord trunk lines.
2. Lack of proper stemming material.
3. Inadequate stemming height.
4. Overdug or overloaded front row holes, collars or burden near the crest too small due to backbreak.
5. Delay sequence.
6. Atmospheric conditions such as temperature inversions or wind in the direction of concern.
7. Secondary blasting.

The first item can often be eliminated as a hazard by going to lower grain count primacord trunk lines or Nonel, covering with drill cuttings, or using electrical blasting. Overdigging or overloading of the front row of holes can be eliminated by flagging for the shovel operator and the stemming heights in the body of the blast increased, but this has to be balanced vs. the top fragmentation. The blasts can be laid out so that a smaller number of holes are fired per delay period. Plaster or mudcap shooting is particularly hazardous in this regard with most of the explosive energy going into air blast.

Delays can be used to isolate the effects of one charge from the next in secondary blasting. Arrange for an approximate minimum of 50 millisecc to lapse between the arrival of the noise from the successive shots. If the closest one is fired first, then the delay to be used can be calculated by dividing the distance difference between the two shots by the sound speed 335 m/s (1100 fps), and subtracting this from 50. Perhaps a good rule of thumb might be to shoot the closest shot first with all others having delays between them of 50 millisecc. Care should be taken to ensure that the blast wave from one shot does not dislodge the next.

When a blast is well stemmed with 12-mm (0.5-in.) crushed rock material and is initiated electrically or with a low energy system such as Nonel, then the front row of the blast is the major area of concern. For example, if the face moves out, it drives the air ahead of it like a piston. If the blast is initiated to produce a row by row blast, then this piston effect is more pronounced and the air blast is enhanced compared to shooting the blast en echelon. However if the en echelon blast is initiated at the furthest point from the observer, then the effect observed depends upon the spacing and delays chosen.

The peak overpressure at a given point is influenced by atmospheric conditions particularly at long distances away from the blast. Wind and temperature altitude profiles have the major influence. The speed of sound in air

$$C = \sqrt{\frac{\gamma P}{\rho}} = \sqrt{\gamma nRT}$$

where T is temperature, γ is the ratio of specific heats, P is pressure, ρ is air density, R is a gas constant, and n is the number of moles so that increases in temperature cause increases in sound speed.

Fig. 44. Effect of altitude temperature profiles on air blast propagation (Edwards and Northwood, 1960).

Fig. 44 shows typical atmospheric temperatures (Cook, 1958), conditions which can occur, and the potential problems associated with temperature inversions or with an increasing temperature with altitude profile. These conditions if they exist can increase the peak overpressure by as much as a factor of five.

In situations in which air blast from production shooting can be a problem, it is often customary to fire a small surface shot and measure the peak overpressure at the point of interest. If the reading is normal, then the main production shot is fired. If it is excessively high, then the blast will be delayed. However, unless the mine equipment has been scheduled for other areas, then this is not a very attractive scheme since the time lost could be considerable. If airports are close by, then the local meteorological information can be used in determining the hazard. If winds are in evidence then inversions will be absent, and one can also obtain information from how the smoke rises from smokestacks, whether it rises initially and then spreads out.

6.2.2 Design of Blasting Rounds

RICHARD L. ASH

INTRODUCTION

For mining competent materials, the production cycle begins with the blasting, the results of which affect all subsequent operations. Improper blasting causes economic and operational difficulties and can create serious safety and environmental problems, particularly when conducted near inhabited areas. It is important, therefore, that all blasts be carefully designed at the onset so they are compatible with the mining conditions and surroundings. It is no longer acceptable to blast without careful advance planning. For all practical purposes it can be assumed all blasts will use explosives confined within a number of boreholes (Fig. 1).

Primary requisites for a successful blasting round from an operational standpoint are that it provides a sufficient quantity of suitably fragmented and properly placed material at the lowest practical cost, possesses adequate flexibility in its basic design to accommodate changing mining conditions, be relatively simple to apply, and generates as few objectionable side effects as possible. A well designed blast is a controlled blast, with the blasthole pattern so arranged that best advantage is obtained from the explosives' energies, the properties of the material being blasted, and all environmental and operational factors present at the mine site. It is the purpose of this discussion to review the significant variables and relevant engineering principles and to present helpful guidelines by which to design blasts for surface mining conditions.

GENERAL CONSIDERATIONS

Blasting is basically a three-dimensional work process, involving the conversion of chemical energy from explosive compounds into gas pressures applied to perform mechanical work. An explosive confined within a borehole functions much like the air and fuel mixture in the internal combustion engine. The work is accomplished during blasting by the generated gas pressures loading materials in such a way that they are displaced, or moved, causing them to fracture. To design a blast, therefore, requires a working knowledge of the capabilities of explosives, how they function in boreholes, and how materials respond to explosive loadings. Because it is quite likely that most explosives used will be the relatively insensitive blasting agents, close attention must be given to the priming, confinement control, and selection of charge diameters that will ensure complete explosive reactions. For purposes of this discussion all products employed for blasting will be termed as explosives whether or not they are defined technically as such.

Characteristics of Explosives

Industrial explosives are a relatively inexpensive energy source but a very powerful tool, having mechanical work-energy equivalents that may range in value from some 167 kJ/kg (5×10^5 ft-lb/lb) to in excess of four times that amount. The explosives are essentially mixtures composed of two or more chemical ingredients that are combined in such a way they will react exothermically after being ignited to quickly form gaseous pressures and sudden heat releases. Pressures developed may vary from as low as 1.4 up to about 13.8 GPa (0.2 to 2.0×10^6 psi) depending on the particular

explosive mixture. There must be adequate ignition energy provided and suitable temperature and pressure conditions present to properly initiate, then sustain an explosive reaction.

Important Properties: Explosives are characterized by several interrelated properties that affect their performances in the field and are always considered when selecting a product for use. An explosive's density, sensitivity, velocity, water resistance, and fumes are the most important properties; although strength is considered by some people also to be significant. The shock energy and expanding gas energy ratings obtained from underwater tests provide the best measure for comparing explosive strengths according to most explo-

B - BURDEN L - LEDGE HEIGHT
J - SUBDRILL H - HOLE DEPTH
T - STEMMING P - PRIMER
PC - CHARGE LENGTH

Fig. 1. Blasthole nomenclature.

sive engineers and scientists. The average blaster, however, normally cannot directly relate such strength ratings to field practice in a practical way.

An explosive's density determines the quantity on a weight basis that can be loaded into a given volume. As a general rule, denser explosives provide more energy per unit volume and are usually preferred where drilling is expensive. The three commonly used density ratings are specific gravity SG_e , loading density d_e , and mass density ρ_e . For approximation purposes, one can consider that most explosive products will fall within the range of 0.8 and 1.6 sp gr, the ρ_e values being the same but expressed in g/cc. Loading density, which depends on an explosive's specific gravity, provides the explosive's weight that would be contained within a cylindrical volume (as for a borehole) with a given charge diameter and unit length. A useful expression for calculating loading density is as follows:

$$d_e = 7.854 \times 10^{-4} D_e^2 (SG_e), \text{ kg/m} \quad (1a)$$

in which D_e is the explosive's diameter in mm. If the explosive's charge diameter is in inches and d_e is desired in lb/ft of explosive charge length, the relationship would be

$$d_e = 3.405 \times 10^{-1} D_e^2 (SG_e), \text{ lb/ft} \quad (1b)$$

Fig. 2 provides a graph for approximating d_e values in lb/ft.

The sensitivity of an explosive refers to its ease or susceptibility for initiation, while its sensitiveness applies to the ability for a reaction once started to propagate continuously. The common standard for initiation sensitivity is termed the minimum booster. When unconfined, a product that can be initiated by a No. 8 test blasting cap is considered cap sensitive and classifies the product as an explosive. A product that requires more initiating energy when unconfined is classified as a blasting agent. Sensitivity is important to consider because it provides a measure of the required initiator's strength and relative safety in handling for a product, as well as its susceptibility to sympathetic initiation from blasthole to blasthole. The quality of sensitiveness, or sensitivity for propagation, is commonly expressed in terms of the explosive's critical diameter, which is the smallest diameter at which the product can sustain a reaction.

The reaction velocity v_e , frequently referred to as the detonation velocity, is the speed at which an explosive's reaction propagates. However, an explosive may react but not detonate if unfavorable conditions are present. The velocity's importance is that it is directly related to the detonation or shock pressure P_d that will be developed and the explosive's acoustical impedance, defined later. The velocity is also useful for estimating primer location design requirements. How significant velocity is to the rock fragmentation process is a source of debate among many experts. Various factors can affect the velocity's value including the explosive's specific chemical formulation, the ingredients' particle sizings, mass density, amount of water present, degree of confinement, charge diameter, and amount of applied initiating energy. The range of v_e values for most commercial products is from 1700 to 7600 m/s (5500 to 25,000 ft/s) as illustrated in Fig. 3.

An explosive's water resistance is its ability to withstand exposure to water without losing efficiency. The two primary effects from water that can result are cooling of a reaction and possible leaching out of soluble ingredients. Both effects can alter the reaction process, resulting in a lower energy release and the generation of toxic gases, or the explosive may misfire. The visible emission during a blast of reddish-

Fig. 2. Explosive densities as a function of charge diameter.

brown nitrogen oxides often indicates an inefficient reaction caused by water deterioration of mixtures containing nitrate compounds.

The fume rating for an explosive provides an indication of the amount of toxic gases generated by the product's particular chemical mixture when tested under certain prescribed conditions. The importance of potential fume generation by a given product is as applicable to surface blasting as it would be in underground usage. This is because certain fumes are heavier than normal air and can be trapped in muck piles and lay in pit bottoms. The oxides of nitrogen are particularly hazardous gases possessing such characteristics. Carbon monoxide is another toxic gas that could be produced but is slightly lighter than dry air; but where humidity is high it may be intermixed in the local atmosphere.

Initiation and Propagation Mechanisms: An explosive's initiation is thermal in origin, beginning as combustion at minute explosion centers known as hot spots. Voids in the explosive are necessary for hot spots to form. If too few voids are present, the explosive cannot react satisfactorily and is called dead pressed. The initial combustion, or oxidation chemical reaction from which heat and light are evolved, begins comparatively slowly due to the requirement to build

Fig. 3. Reaction velocity variations with charge diameter for selected explosives.

up a critical concentration of reactants. Whenever the heat generation rate exceeds that lost due to convection and conduction, the gas pressures continue to grow, accelerating the heat generation and attendant pressure rise. As the number of hot spots increases and spreads throughout an explosive, they consolidate into a pressure front. When the combustion transcends into a rapidly progressing, relatively self-sustained, and near-spontaneous oxidation with high heat and pressure formation accompanying the reaction, it is called deflagration. If the rapidity of energy release continues to increase so that compressional waves are propagated through the unreacted portion of the explosive in excess of its characteristic sound velocity, a low-order detonation results. When conditions are favorable, temperature, pressure, and velocity gradients may continually grow steeper until a stable, fully developed detonation results, with its supersonic shock wave preceding the combustion zone. Fig. 4 illustrates an explosive column that was initiated at one end with a full detonation positioned halfway through the column.

Adequate confinement for explosives is necessary because it minimizes temperature and pressure losses. Also, since reaction products expand laterally as well as longitudinally, both the charge diameter and length must be large enough to not hamper movement of the reaction. Those dimensions are related geometrically to the explosive's characteristic reaction length. Most high explosives have short reaction zones and smaller critical diameters than do the blasting agents.

To ensure rapid formation of hot spots and prompt development of high-order detonation in a main explosive charge, a good primer must be employed to provide adequate heat and pressure quickly over as large an area as possible.

A primer is a cap-sensitive explosive unit containing an initiating device; a booster is an explosive used to intensify an explosive reaction but it does not contain an initiator and may or may not be cap sensitive. A primer is considered satisfactory if it has four minimal qualities: cap sensitivity, an SG_c of 1.2 or higher, a v_c of at least 4600 m/s (15,000 ft/s), and immunity to the environment. An explosive satisfying the density and velocity minimum requirements will develop a detonation pressure of approximately 80 kb (1.2×10^6 psi). Immunity to the environment requires that the explosive be unaffected by water, diesel fuel oil, normal ambient temperatures, lack of confinement, and poor storage conditions. Ideally, the primer has a diameter that matches as closely as possible the diameter of the explosive it is to initiate for maximum efficiency, or is sufficiently greater than the critical diameter of the explosive used as a blasthole's main charge.

The ideal gaseous products formed by a properly oxygen-balanced mixture consist essentially of some combination of nontoxic carbon dioxide, inert nitrogen, and steam. If aluminum, calcium, or sodium, for example, is included in an ingredient and a reaction is complete, a metallic oxide such as Al_2O_3 , CaO , or Na_2O will be produced as a solid residue. The difference between the sum of the heats of formation of the products generated and the sum of those heats for the initial ingredients determines the maximum amount of heat that can be potentially released by the reaction of an explosive. The values thus obtained for various mixtures, termed their heats of explosion Q_e in kcal/g, are considered by some persons as their respective blasting capabilities. Use of Q_e to rate explosives, however, is misleading because explosives are employed to provide pressures and not just heat. A more useful rating than kcal/g is the mechanical equivalent of work expressed in terms of joules per gm or ft-lb/lb, which relates both the potential heat content and gas volume produced.

Explosives' Pressures: As illustrated by Fig. 4, there are two distinct and separate pressures generated by explosives during blasting: that from detonation P_d and that from the explosion products P_e . Each has its own unique characteristics. Since P_d results from physical movement, its value is

Fig. 4. Characteristics of a detonation reaction.

Fig. 5. Pressure-time profiles for explosive reactions.

a function of the kinetic energy generated and is proportional to the product of the first power of the explosive's mass density and the second, or squared, power of the reaction velocity. Therefore, if an explosive reacts at one-half its ideal rate, the detonation pressure will be only one-quarter of its maximum theoretical steady-state value (Fig. 5). On the other hand, the pressure from the reaction products, more commonly called the borehole pressure, is independent of the reaction velocity and is produced regardless of whether or not the explosive detonates. The magnitude of P_r will be a function of only an explosive's chemical composition, density, and that its reaction went to completion. The borehole's pressure value, although directly proportional to an explosive's density and to the amount of heat released by the chemical ingredients, will be inversely proportional to the volume of gas produced. Therefore, explosives generating higher amounts of heat but lesser gas volumes provide greater borehole pressures, a quality that distinguishes many of the aluminized explosive mixtures.

The unit borehole pressure, i.e., psi, ideally will remain constant irrespective of charge diameter for a fully confined explosive; although the total force produced and charge weight per unit length that is used will vary in direct proportion to the ratio of the diameters squared. The detonation pressure, on the other hand, may be reduced if the charge diameter is decreased within the range below the minimum value necessary for a full detonation to develop (Fig. 3). If confinement is reduced such that a volume change results, then both the borehole and detonation pressure magnitudes will be lower. For explosives with poor initiation and propagation sensitivities, too great a volume increase can cause them to misfire, or in some instances to simply burn. Therefore, cap-sensitive explosives with good propagating characteristics must be used under poor confinement conditions

and when engaged in practices such as presplitting and trim, or cushion, blasting.

Ground Conditions

In the development of a blasting round it is essential to first consider the physical characteristics of the materials to be blasted, even before selecting the borehole size and explosives to be employed. Frequently, several geologic material types will be encountered when blasting, with only the competent and relatively hard materials requiring explosives. Rocks as materials are neither homogeneous nor isotropic by nature. Because the various rock types are more or less unique as to their mineralogical composition, hardness, structure, and texture, there will be differences in their responses to loading, fracturing, and energy transmission capabilities (Table 1). It is essential, therefore, that the blast designer be fully knowledgeable of the various geologic material types and their respective characteristic properties.

Of the three basic rock types, the igneous rocks as a group are characterized by a crystalline texture with a mechanical interlocking arrangement of their respective mineral components. Exceptions are the glasses, lavas, and tuffs. Igneous rocks are usually quite coherent and have textures that are closely similar in all directions. The finer the grain sizing

Table 1. Relative Hardness of Rocks

the greater the strength, and many of the rocks will have comparatively high sonic velocities. As materials, they are strong and break in a brittle fashion, being quite elastic and dense with low or negligible porosities.

Sedimentary rocks have widely varying strengths, definite and pronounced structural and textural orientations of the constituents, and highly variable porosities and energy propagating velocities. The mineral aggregates are bonded together either chemically or have a cementing agent as a matrix. Limestones and dolomites, for example, are usually quite strong with medium-rate and relatively stable sonic velocities. The sandstones, however, exhibit light densities, low strengths comparatively, and propagation velocities that often decrease with travel distance away from the impacting source until a lower level stable rate is attained. Sandstones also may have porosities that are particularly susceptible to saturation with water. Shales, on the other hand, are fairly dense and nonporous but are very weak due to their highly platy or laminated structure.

The metamorphic rocks such as marble, quartzite, and slate, for example, possess properties of both the igneous and sedimentary types. Because they were formed from the other two primary types of rock as a consequence of added heat or pressure, or a combination of those agents, the metamorphics are usually quite dense and strong. Their energy propagating characters are such that they frequently exhibit high sonic velocities.

Density and Swell: The significance of density in blasting is that as a rule one could expect more energy and thus more work to be required for displacing and fragmenting the heavier materials. Most dense rocks are stronger and tougher. Density of in-place rocks may be expressed in three ways: as ordinary density, d , in kg/m^3 (lb/ft^3), as specific gravity, SG , that is unitless, and as mass density ρ , in g/cc ($\text{lb}-\text{s}^2/\text{ft}^4$). The ρ , is usually employed in theoretical calculations such as when considering a material's dynamic energy transfer property or acoustical impedance. The latter is the product of a material's mass density and its compressional wave velocity.

Except for the very heavy iron ores with densities of about $5 \text{ kg}/\text{m}^3$ ($310 \text{ lb}/\text{ft}^3$), most ores and rocks requiring blasting have in-place densities in the 2 to $3 \text{ kg}/\text{m}^3$ range (125 to $187 \text{ lb}/\text{ft}^3$). For first approximations, an average SG , of 2.65 , or d , of $2.12 \text{ kg}/\text{m}^3$ ($165 \text{ lb}/\text{ft}^3$) can be used for most materials without introducing excessive error.

Although not strictly a property like density, the swell, or expansion, of material when broken from the intact or solid condition must always be considered for blast design (Fig. 6). The swell factor S_f will be unique for a given material and fragmental sizing mix. It is defined as the ratio of the volume of a unit weight of intact material to that when broken. The factor's value will usually be greater than 0.5 and less than 1 . Table 2 lists approximate S_f values for various earth materials considering average sizing mixes. A good mean value of S_f for estimating purposes is 0.7 , or as a rough approximation, it is common to assume that there will be a normal expansion of 50% , or half again, the original in-place volume when the material is broken out of the solid bank.

As shown by Fig. 6, minimal volumetric expansion during ordinary bench blasting occurs in two directions for a box cut, while for the corner cut the expansion will be in three directions. If swell is assumed to be uniform, each solid dimension toward an open face could be expected to expand to an amount at least equal in value to the initial solid dimension divided by the material's characteristic S_f value to a root power equal to the number of open surfaces. For the box cut the factor would be $S_f^{1/2}$, while $S_f^{1/3}$ would be appropriate for a corner cut.

The effects of swell must be accounted for in designing not only a blast's entire volume but also for the respective volumes of each row of holes and those for each individual blasthole fired independently or set of holes initiated with close interval firing times. Otherwise, the displacement necessary for proper fracturing and displacement of the broken material as holes are fired will be impeded. Failure to leave adequate space for expansion is a major contributing cause for airblast, excessive flyrock, intensified ground vibrations, overbreak, toe, uneven pit floors, and difficult digging caused by packing.

Geologic Structure: Competent blasters all recognize that rock structure exerts a most important, if not dominant, influence on the results achieved from blasting. Discontinuities such as jointing, stratification, foliation, schistosity, faults, and unconformities all serve as natural planes of weakness along which a rock mass will separate the easiest. The planes control not only the locations where fractures will most likely start but also the directions or paths along which breaks in a material once initiated can be easily extended. Most discontinuities can be detected and recognized by their

Fig. 6. Swell during bench blasting.

Table 2. Approximate In-Bank Weights and Swell Factors

more or less continuous flat surfaces when exposed. Caves, cliffs, mud seams, and the general trend of river channels through rocky ground show a preference to follow such structural orientations.

Jointing is present in all rock types. Joint planes always occur in sets, one of which is parallel or nearly so with a rock formation's dip and strike with two or more in number oriented approximately perpendicular to the first set of planes. Joints may be tight, open, or filled, thus exhibiting different strength and stress-energy propagating properties. As the number of differently oriented planes increases within a rock mass, the less competent it becomes. For materials having joint planes of uniform strength and with nearly equal included angles, blasting patterns are relatively simple to design. The igneous rocks as a group will approximate this condition, with angles between joint planes being near 60° .

Sedimentary and certain metamorphic materials, however, present a different condition, and balancing an explosive energy is more difficult to achieve. In this case there is usually one particular direction along which joints are most pronounced, and angles between the various sets frequently are not equal. Such a condition presents situations where there will be two opposite tight or acute-angled corners and two wide-angled parts within an area (Fig. 7). Blastholes located in the tightly jointed areas always tend to aggravate ground vibrations and cause overbreak, opening cracks along the jointing planes back into the solid ground. To reduce adverse effects, blasts are best directed out of the wide-angled locations whenever possible, and perimeter holes should be aligned with the dominant joint set. Serious backwall problems can arise from overbreak when alignment is crosswise with joint planes (Fig. 8).

It is important to note that for jointing there was no visible movement parallel with the planes. If a joint is tight and contains no filling, stress wave energy passes through the joint as if it were not there since there is no change of material's properties on either side. However, if filled with

Fig. 7. Plan view of vertical joint system in sedimentary rock.

Fig. 8. Example overbreak damages from holes not aligned with joint planes (Bauer, 1978).

different material or open, the joint will function as an impedance discontinuity, providing a location for scattering of stress waves. A fault, on the other hand, involves an offset of material on either side of a failure plane and usually coincides with the direction of jointing. More often than not there also will be some gouging or scouring of material within the fault zone. Thus, a fault provides a failure plane at which separation is easy as well as where stress wave energy can be reflected and dispersed.

Stratification exists where sediments are deposited in beds or layers and results from interruptions in the deposition process. The material on one side of a plane has a somewhat different lithology than that on the other side. The planes separating the various strata normally offer virtually no resistance to movement and are commonly referred to as partings or slip planes. If a bed is thick and massive except for its transverse jointing, uncontrolled slippage can lead to the production of large slabs or blocky rock sections, high bottoms, and possible blasthole cutoffs. Where beds are inclined, additional problems may be presented. For example, beds dipping downward into a bench or highwall provide a condition for possible toe development and uneven pit floors but with a relatively stable bench wall. On the other hand, beds that dip upward into a highwall can leave a gouged-out pit floor as well as an unstable final wall (Fig. 8).

Banding such as foliation and schistosity as found in certain metamorphic rocks responds to blasting much like

bedding. The coherence of this class of rocks will depend on the minerals present. For example, as the amount of constituent mica increases, the competency decreases. Failure under stressing is always favored along the mica orientations when sufficiently concentrated. Foliation is the general term applied to the laminated structure resulting from segregation of different minerals into layers in metamorphic rocks while schistosity is foliation occurring in the coarser grained rocks containing micaceous minerals.

Unconformities, as opposed to bedding planes, are generally irregular and have materials on either side with quite different properties. They were formed where there was a long period of time elapsing between the deposition of the younger material on older-age rock that had been subjected to erosion or long weathering.

Energy Transmission and Ground Water: As pressures are produced within a blasthole, the surrounding rocks respond by developing stresses and their related strains, or internal deformations. The initial rapid loading effects of the pressures are that only a portion of the rock mass is affected at any one time, an action by which particles within the mass are set into vibrational motions. Thus, compressional or sonic waves from in-line movements and distortional or shear waves from sideways displacements will be generated, which traverse through the rock mass at different rates. A particle is in motion for only a short time, and once set in motion has a maximum velocity when it passes through a position of zero displacement. The rate of travel of particle movements through the ground by the compressional action v_p is faster than the rate of lateral motion travel v_s . Thus, at a given point in the ground away from a blasthole, the longitudinal or compressional motions arrive first with sideways movements occurring shortly after. The surface wave-type motions are generated wherever the compressional and shear body waves encounter open ground surfaces. The energies of the surface waves travel at lower rates and decay more slowly with distance than those of body waves. The formation and propagation of surface waves are favored by pronounced geologic layering.

In the design of blast, the ground's characteristic sonic velocity v_p should always be taken into account (Table 1). First of all, the greater the match between the ground's acoustical impedance $\rho_p v_p$ with the explosive's impedance $\rho_e v_e$, the greater will be the amount of dynamic or shock energy transferred into the ground when the explosive first reacts. However, in a practical sense, the amounts will be low in most instances because of the large difference normally present in the respective ρ and v values. Only where dense explosives with high reaction rates are used are impedance mismatches kept to a minimum. The practice of decoupling such as used in cushion blasting, for example, uses the principle of providing the greatest possible mismatch of impedance for the expressed purpose of minimizing dynamic shock transfer.

The combination of the ground's v_p and explosive's v_e , charge length PC , and primer location is important also because it determines the shape of the composite stress front generated within the ground from each successive point along an explosive column. As shown by Fig. 9 for end-initiated blastholes, a conical stress form develops when v_e exceeds v_p . If the velocity ratio v_e/v_p is equal to one or less in value, the spherical form is developed. In this latter case, the resultant effect is one by which each incremental stress generated by successive points along a column reinforces those induced earlier. For columns that are center-primed, or initiated simultaneously at both ends, the stress forms where v_e exceeds

Fig. 9. Stress wave forms from end initiated blastholes.

v_p will be merely double images of those for the single end-primed conditions.

Depending on the degree of saturation, fracturing of wet ground during blasting can be more extensive than when it is dry. Under wet conditions more than normal collar stemming amounts are recommended to control possible airblast and flyrock. The presence of water in ground has the effect of reducing the ground's compressibility, causing it to be less capable of absorbing strain energy. Because of wet ground's increased rigidity, the generated lateral strains are greater for the same applied longitudinal compressive strains, decreasing the ground's compressive and shear strengths. A blasting design, therefore, should include provisions to account for changed moisture conditions, particularly for the control of possible intensified detrimental side effects.

BLASTING MECHANICS

The purpose of blast design is to distribute explosive energy in such a way that certain fragmentation and muck pile displacement requirements will be satisfied. The primary means by which this is accomplished is by selecting the proper borehole size and locating the respective boreholes making up a round in their proper positions. To develop a suitable pattern, however, requires a working knowledge of a borehole's blasting characteristics when acting independently and together with other blastholes.

Because of its cylindrical shape, the typical blasthole directs most of its energy laterally, or perpendicular to its axis, not equally outward in all directions as does a spherical idealized charge. For that reason the burden dimension B is generally measured perpendicular to a borehole's length. The directional effect occurs from the fact that most of a hole's surface area against which explosive pressures act lies in a blasthole's sidewall. The condition becomes apparent when one thinks of a hole as a pipe or tube whose respective areas of surface could be described by the expression

$$A = 1.57D^2(2L/D + 1), \quad (1)$$

in which A is the total area and D and L are the diameter and length, respectively. In the expression the $2L/D$ ratio is that share of the total area contributed by the sidewall while the 1 represents the portion due to the sum of the two ends. Thus, for many blastholes whose lengths are commonly sixty or more times their diameters their sidewalls contain over 99% of the surface area. Even when lengths are shorter and diameters proportionately increased, the sidewalls still

contain most of the area. For example, a typical 12-inch diameter borehole bulk-loaded with a 20-ft long explosive column has 95% of its area in the sidewall, and a cylindrical point charge with equal diameter and length still has a sidewall area equal to two thirds of the total surface. In the event that it is desired for blastholes to crater toward their collars, it follows, therefore, that the largest possible diameters with very short charge lengths should necessarily be used even though the largest area for which the pressures will act would remain present on the hole side.

The actions of the two pressures are unique for the usual blasthole. Unlike the results caused by the detonation pressure generated by a concentric charge, the pressure produced by an explosive confined within a borehole is usually not effective. For a borehole the detonation pressure's energy is directed primarily axially through the explosive's column center. As a consequence of the detonation front's rapid movement through the column, the pressure is directed at an angle into the sidewall, reducing its thrust's effectiveness against the surrounding rock. Furthermore, the pressure's contact area is such that only a small portion of the borehole's rock surface is affected at any time instant, which moves as a very narrow circle of pressure that proceeds from the primer in progressive order along the wall to the charge's opposite end at which point the pressure is terminated (Fig. 4). The borehole pressure, on the other hand, undergoes a rapid pressure buildup at the explosive's reaction rate at the end of which it stabilizes at its full value to pressurize the entire surface area of the explosive chamber. It follows, therefore, that the borehole pressure is the dominant cause for rock breakage in field blasting, and it is the near-sudden buildup of that pressure in a borehole that is the major cause for generating ground vibrations from blasting.

Rock Breakage Mechanisms

Three distinct processes can break rock during blasting: slabbing from stress wave reflection, radial fracturing, and flexural rupture. True slabbing by reflection of stress waves, however, is considered absent or at least negligible under conditions normally present in field blasting. For slabbing to result, a free surface must be present at a burden distance within twenty borehole diameters to be even detectable.

Radial fracturing, or the formation of cracks oriented in lines with a borehole, results from tangential or hoop stresses generated in the rock surrounding a blasthole. The cracks can be initiated in a borehole's sidewall by both the deto-

nation and borehole pressures if their respective energies are sufficient to overcome the rock's tensile strength. Fracturing in the sidewall results when pressurizing of the borehole cavity causes the wall surface to expand or stretch. Crack initiation by the detonation pressure is short-lived however, because of the momentary applied nature of that pressure. Cracks can also be started in the ground away from a borehole by stress waves as they encounter voids and other impedance discontinuities, providing particle motion stress levels at such locations produce strains sufficient in strength to cause tensile dislocation. Crack initiation by stress waves also is brief because stress waves quickly outdistance the cracks, whose peak velocities can approach only from 0.15 to 0.40 times a ground's sonic velocity.

Radial cracks form in a borehole wall initially at a primer, developing fracture planes that parallel the borehole axis as the explosive column reacts. The cracks form, however, only where explosive energy is located. Extension of cracks once started is accomplished by the borehole pressure as it loads the surrounding ground. As long as adequate strain energy is present at crack tips, the fractures will continue to extend, following paths that are normal to the maximum principal tensile stresses. More energy is needed to start cracks than to extend them, and as cracks become longer less and less pressure is needed for further extension. The extension process occurs in a similar manner to a wedging or splitting action.

Where there is only one free face in which a borehole collar is located, the radial cracks form a symmetrical pattern about the hole. In that the ground can displace only toward the single free surface, an uplifting of the collar rock results, causing cracking to extend to the surface. The result is a loosening of the collar rock and hole stemming and this always causes some airblast and flyrock. Use of excessive burden distances to the sides of holes produces a similar effect.

If there is a second free face located parallel or nearly so to a borehole, radial cracks will begin to distort toward the second face as it is brought closer to the hole. Because of the open surface to the side the high pressure forces the ground in between to displace toward that face, causing the borehole to assume an elliptical shape oriented perpendicular to the side surface. The extended sides of the hole, thus, are placed in greater tension than are the hole portions nearest and farthest from the side face. As the burden is reduced even more to the side face, the cracks reduce in number as well as extend more from the hole's sides until they intersect the side face. Where a borehole is properly located, there is little or no radial cracking in back of the hole and collar overbreak is generally absent. With the addition of a third free surface, or two side faces as on a bench corner, the effect is to offer further reduction in resistance for the radial cracking process as long as the two side faces are located at closely similar distances from a blasthole.

The outer edges of the radial crack system define the limits of the blasthole crater formed (Fig. 10). Two factors determine the crater's apex angle: the orientations of the geologic structural planes and the relative distances from a borehole to all open faces. A narrow crater apex angle with back shatter always indicates an excessive side burden. A borehole with but two open faces will have a crater apex angle that may vary from as little as 60° up to as broad an angle as double that amount. As the burden distance decreases the apex angle widens up to its maximum value. The reverse effect occurs as the burden distance increases until a crater angle of about 60° is reached; below this point the

Fig. 10. Basic crater forms.

intervening rock becomes difficult, if not impossible, to be displaced outward. If three free faces are present, the crater formed has an apex angle from about 135° up to 180° . In this situation the preexisting corner angle as well as distances to the two side surfaces will determine the resulting crater angle following blasting. For estimating and general design purposes, however, it is customary to assume a 90° apex angle for craters obtained from blastholes having two free faces and 135° for the three free-faced condition.

The segments of rock bounded by radial crack planes are fixed in place where stemming is used and at borehole bottoms if no pronounced discontinuity planes are present along which easy slippage can occur. The breakup of the intact rock segments, however, is accomplished by flexural rupture through bending of the segments as they are displaced outward by gas pressure expansion action. The bending action occurs in both directions, i.e., in the hole's length plane and its diameter plane, the process being clearly visible during any blast. Rock movement and the accompanying bending action occur shortly after radial fracturing is completed, the initial movement beginning after a time lapse following a blasthole's firing of about 3.3 ms/m (1 ms/ft) of burden distance. Without the flexural rupturing complete breakup of burden rock would not be possible.

Burden Rock Stiffness

Breakup of rock from flexural rupture by a blasthole is controlled by the stiffness condition of the burden rock. The principle of stiffness can be easily understood if it is recognized that a thick short block is always more difficult to break by bending than would be a long, slender, more flexible segment of material. In applying the stiffness concept to blasting, the burden rock on a single blasthole when radially cracked can be considered as a modified rock beam with a fixed hole bottom and collar zone that is restrained but allowed to rotate. In the case of several blastholes fired together, or fired at close-interval timing so their burden rocks respond more or less as a single unit, the combined rock mass would function like a wide beam or plate.

As with any beam structure, the stiffness property K of a blasthole's burden rock defines the amount of loading force or pressure needed to produce a unit external displacement. According to ordinary beam theory, the value of K will vary directly with the product of the beam material's Young's

Modulus, its width, and the third power of the ratio of its thickness to its length. In terms of the burden rock on a single blasthole, therefore, the applicable relationship for its stiffness can be represented by the following expression:

$$K \sim E_s(B/L)^3, \text{ N/m (lb/ft)} \quad (2)$$

in which E_s is the elastic modulus of the rock, S is the average crater width or borehole spacing, B is the burden dimension, and L is the open face length paralleling the blasthole (Figs. 1 and 10). From the expression it can be seen that the stiffness character of burden rock is independent of the applied pressure but is linearly proportional to the rock's modulus of elasticity.

The B/L ratio is of particular significance to the stiffness of burden rock because of its compounding effect. For example, with restraint conditions, charge spacing, and bench height constant, doubling the burden dimension will increase the stiffness by as much as eight times. On the other hand, for a blasthole with its burden and spacing dimensions unchanged, increasing the bench height by just 25% reduces the burden rock's stiffness to one half that existing previously. In other words, relatively minor changes in either the burden or bench height with the other dimension remaining constant will cause large adjustments to the stiffness condition of burden rock.

Reductions in stiffness are greatest when B/L ratios are decreased within the 1 to 0.5 value range, the reductions becoming less and less significant with each incremental additional decrease in ratio. Because of the stiffness effect the use of larger diameter holes with their greater burdens for relatively short bench heights invariably produces coarser fragmentation and a potential for developing problems of stronger ground vibrations, overbreak, and the like. To avoid the problems resulting from excessive stiffness, therefore, it is recommended that as a rule blasthole burdens should be limited at a maximum to one half or less the bench height dimensions. Fig. 11 is a set of plots obtained by finite element analysis showing the initial displacements resulting during the bending process for three different bench height conditions with a common burden dimension.

In much of blasting, the hole collar and bottom regions often cause the most problems. At both locations the flexural tensile stresses are maximum at the explosive charge ends, causing the fractures to start at the borehole and then extend

Fig. 11. Bending conditions during bench blasting (Smith, 1976).

BACK-BREAK VS. BACK-SHATTER

Fig. 12. Effects from excessive burden rock stiffness (Anon., 1975).

toward the open faces. The movement action of the collar zone is normally one of rotational uplift produced by the bending action of the burden rock below. Backbreak at the collar results where the rock mass in that region is too stiff to break completely through at the borehole (Fig. 12). In this case the amount of unloaded or stemmed hole collar relative to the burden dimension, or T/B ratio, controls the stiffness of collar rock in the same way the B/L ratio affects the bending capability of the lower burden rock (Fig. 1). To reduce the stiffness, radial fracturing must be raised higher toward the hole collar so as to reduce the rock's thickness between the explosive charge and open collar face. Figs. 13 and 14 illustrate three techniques for solving the problem as may be appropriate for the conditions.

Bending at the hole bottom is similar to that at one end of a beam fixed at both ends and is necessary to eliminate toe if there is no free parting at that location (Fig. 15). Normally drilling below grade level prevents toes. The effect of the subdrilling is that it lowers the position of the max-

TOP BREAKAGE IMPROVEMENT

Fig. 13. Example techniques for breaking collar rock (Anon., 1975).

Fig. 14. Satellite charge and stemming applications.

imum moment during bending so fractures can proceed perpendicularly from the borehole to the open face at floor level. However, subdrilling will be of little help if the upper burden rock cannot be moved outward in advance by bending because it is too stiff.

BLAST DESIGN GUIDELINES

There are nine design variables normally considered as important and over which the blaster has some measure of control when designing a blasting round. Six of the factors are dimensions: the explosive's charge diameter D_c , the blast-hole burden B , collar stemming T , subdrilling J , and hole length H , and the spacing distance S between adjacent holes. The remaining three variables are the explosive's specific gravity SG_e , the primer locations P , and the respective firing times of the blastholes. The various factors are all interdependent with values for the dimensional ones having been determined empirically. Frequently certain of the variables are combined in the form of dimensionless ratios such as the burden in terms of the charge diameter, stemming as a function of the burden, and spacing as some multiple of the burden, for example.

The problem with developing a design for a blast is that a blaster must select the combination of variables best suited for the conditions existing at a given site and operation. The recommended procedure is to first consider the single blast-

Fig. 15. Two types of toes resulting from bench blasting (Anon., 1975).

hole and its probable radial cracking and flexural breaking effects, taking into account the ground conditions and being certain its individual design specifications are correct. Secondly, all possible interactions between neighboring blast-holes comprising the round must be taken into account so that the desired overall results will be obtained. In each case tight conditions should be avoided in so far as possible.

Single Blasthole Relationships

The charge diameter D_c is the most critical dimension of the design factors because it controls the explosive quantity at any one location within a blasthole for any given explosive type (Fig. 2). It may also affect the explosive's reaction velocity (Fig. 3), thus influencing the dynamic characters of the borehole and detonation pressures, the shape of the composite stress form generated in the ground, and to some degree the relative frequency of cracks in the blasthole's immediate vicinity. Smaller-diameter holes develop more fractures in their walls than do larger ones because of their greater curvatures. Selection of a specific charge diameter may be restricted, however, because the available borehole sizes will depend on the drill equipment on hand. But wherever possible it is recommended that the D_c be no larger than 0.015 times the bench height L , the limiting point at which the burden dimension will not impose excessive stiffness on the burden rock.

The burden dimension, or B , is defined as the distance from a blasthole to the nearest open face at the time the hole is fired. Normally the burden would be considered in a direction perpendicular to a borehole's axis (Fig. 1), while for the crater type blast it is measured from the upper charge end to the open face at a blasthole's collar. In the latter situation, it is often called the depth of burial. Whether for bench or crater blasting, its optimum value will be that which produces the desired fragmentation and displacement of the broken ground that provides the most efficient subsequent removal. The burden's primary function is that it provides the major control over the directions and extents of radial cracks and is one of the main factors affecting the stiffness character of burden rock. There is no common burden for all explosives and materials; the best dimension will depend on each given situation and should be determined after initial field tests.

For first approximating the burden's value there are a number of relationships. Many formulas utilize charge volume, weight, or diameter as the basic independent variable with the burden, or burial depth, being a function of the cube or square root of the variable. Other expressions consider the burden as dependent on the product of the charge diameter and the square root of the ratio of the explosion pressure to the rock's tensile strength or directly on the square root of the product of the charge diameter and hole length. Still another proposed relationship determines instead the required charge weight for a given burden dimension. In most formulas various empirical constants are included to account for the explosive's and material's properties. Some of the relationships, on the other hand, require initial tests to determine the necessary values for the needed constants. Regardless of the relationship, most provide burden values that are generally comparable within certain limits.

Of the many formulas, a relationship developed from the analyses of numerous field blasts that is relatively simple for blasters to use and applicable for most conditions for estimating the burden is as follows:

$$B = 0.036 D_c (SG_e / SG_r)^{1/3}, \text{ m} \quad (3a)$$

Table 3. Representative Values for Estimating Burdens

Properties of Explosives		
	(Density, SG_e)	(Velocity, v_e , fps)
Minimum	0.8	6,000
Maximum	1.6	24,000
Average	1.3	15,000
Properties of Rocks		
	(Density, SG_r)	(Velocity, v_r , fps)
Minimum	1.92	6,000
Maximum	3.21	23,000
Average	2.65	12,000
$(SG_e/SG_r)^{1/3}$ Ratios		
	(Light Density Explosive)	(Heavy Density Explosive)
Light Rock	0.75	0.94
Heavy Rock	0.63	0.79
Average	0.79	

in which B is in meters and D_e is in millimeters. If D_e is in inches and B is given in feet, the relationship is

$$B = 3 D_e (SG_e/SG_r)^{1/3}, \text{ ft.} \quad (3b)$$

Table 3 lists representative $(SG_e/SG_r)^{1/3}$ ratio values covering most explosive-rock combinations.

The burden may also be estimated on the basis of an explosives loading density d_e as follows:

$$B = 1.087 d_e^{1/2}, \text{ m} \quad (4a)$$

in which B is in meters and d_e is in kg/m of charge length. For the burden dimension in feet and loading density in lb/ft, the expression is

$$B = 3.562 d_e^{1/2}, \text{ ft.} \quad (4b)$$

Fig. 16 illustrates the ranges and trends of B values in ft as a function of D_e in inches and d_e in lb/ft.

To confine explosive gases until they have had time to adequately fracture and start ground movement, stemming material is placed in the collar region of a blasthole (Fig. 1). Crushed rocks of medium to coarse sizings are considered best as stemming; they tend to lock or wedge in the hole when it is pressurized. Since the stemming material must be first compressed before it can be ejected, the confinement occurs as a brief delayed action. Stemming material that is wet or has a low compressibility, such as finely sized cuttings, provides little or only minimal confinement. If the burden

rock below is sufficiently flexible, its bending outward and the accompanying collar rock rotational uplifting action cause the borehole to partially close at its collar, helping to further lock the stemming material in place.

Experience has shown that relatively dry collar stemming for most bench blasting conditions should fill a hole collar a distance T of from 0.5 to 0.7 the burden dimension. A convenient approximation relationship frequently used is as follows:

$$T \sim 2B/3. \quad (5)$$

Because the stemming volume occupies about 1.5 times that of solid rock due to swell when compressed by the explosive gases, the T dimension, or the collar rock's thickness, therefore, will become about 0.5 times the B dimension, i.e., the collar rock's length. The result is to decrease the stiffness of the collar rock, aiding in its breakup by flexure when uplifted, similar to the B/L ratio limit of 0.5 at which burden rock becomes excessively stiff as discussed earlier.

Collar priming requires more stemming than bottom priming as does also a relatively stiff burden rock that inhibits the necessary collar rock uplift. However, too large a T value results in the formation of boulders or blocks from the collar zone with a potential for severe backbreak or undercutting when rock structural conditions are unfavorable. On the other hand, if T is too short, violence in the form of airblast and flyrock with some backbreak could be expected. For

Fig. 16. Chart for estimating blast-hole burdens.

crater blasting in which breakage is intended toward the collar, the T dimension should equal the estimated B value.

Stemming is applied not only in the borehole collar but also wherever it is necessary to confine explosive gases that might otherwise vent such as soft mud seams, open fractures, and the like, or where it is desired not to damage material as with coal (Fig. 14). The two-thirds rule is not normally applied in such cases, or for deck loading, in which, instead of a continuous explosive column, several separated charges are contained in the same borehole to bypass the areas to be avoided. In those situations, the rule is to employ stemming in the amount of about one-third the burden dimension on each side of the hole portion to be left void of explosive.

As a consequence of the particular free face conditions in blasting with a fixed borehole bottom, blastholes must be drilled below floor or grade level in massive ground. The actual amount of subdrilling needed depends on the burden distance, orientation of the blasthole relative to all open faces, and the geological structural conditions at its bottom. If an easy shear plane exists at that location, little or no subdrilling normally would be required. Otherwise, as a first approximation the rule is that the subdrill J should be about equal to one-third the B dimension for hard ground, a relationship used for estimating the subdrill being

$$J \sim B/3 \quad (6)$$

In the event some high bottom remains following blasting or burden rock above is quite stiff, i.e., a low B/L ratio, more subdrill is required but should not exceed one half the burden's value. Excessive subdrilling wastes drilling and explosives, causes intensified ground vibrations, and often leaves fractured and gouged pit floors. To satisfactorily displace bottom rock at a blasthole's toe region, it is always necessary for the burden rock above to be moved first. Faces that are perpendicular to floors are placed in high compression so are more prone to develop toes; angled faces relieve the tightness, thereby usually requiring less subdrill. Bottom-primed holes also generally need less subdrilling than those employing collar priming.

Where the bench height L is a fixed amount the hole length H similarly will be predetermined, the H dimension being the sum of L and J . For an opening sinking cut the value of H is considered to be a function of the cut depth that can be successfully pulled. In that regard a common principle frequently followed is that only about half the narrowest width of the opening cut could be expected to be properly broken. Irrespective of the type of cut, the hole depth must be compatible with the burden dimension if excessive burden rock stiffness is to be avoided with a length of at least twice the burden.

Long hole depths are generally undesirable, particularly when they are of small diameter. Hole lengths greater than four or more times their burdens are subject to potential cutoffs of their explosive columns in layered ground. For the smaller diameters, the error in maintaining proper hole alignment is compounded as length is increased. In addition, having to work at the edges of high bench faces while drilling and charging front rows of holes with their small burdens presents a hazard. Blasts with extra long holes can be difficult to control and should always use multiple primers. To avoid difficulties it is recommended, therefore, that insofar as practical, blasthole lengths should be kept within a range of two to four times their burden dimensions. A relationship for estimating the appropriate hole length H in meters with subdrilling in terms of explosive charge diameter D_c in millimeters is as follows:

$$H \sim 0.097D_c, m. \quad (6a)$$

For a D_c expressed in inches the approximate H in feet would be

$$H \sim 8.1D_c, ft. \quad (6b)$$

It should be noted from the above relationships that for any given D_c , the bench height L would be from two and one-half up to four times the estimated range of B dimensions for most explosive-rock combinations, with an L value of approximately three times B for the average 2.65 specific gravity rock in which a 1.3 specific gravity average explosive is used for the blasting.

The primer position for an explosive column charge determines that portion of the burden rock which is first radially cracked and begins movement (Fig. 9). As hole depths increase, differences in blast effects become more pronounced. Collar priming, for example, usually promotes a waterfall effect, causing the broken material from a blast to be stacked in high piles adjacent to the vertical face. On the other hand, bottom priming tends to throw and spread the fragmented rock over a pit floor. Except where a high muck pile is necessary for efficient loading, bottom priming is the preferred practice from the standpoint of safety and explosive energy utilization. Locating the primer in the hole bottom ensures there will be no unexploded explosive remaining in the bottom after firing and provides maximum confinement, assuming adequate collar stemming is present and the explosive column is not too long. Regardless of primer location, the initiator, or detonator, in a primer should be pointed toward the bulk of the blasthole total charge. Initiators as well as all explosive column charges are very directional in their execution.

Collar, or direct, priming produces an ideal situation for premature collar rock fracturing and movement. Where the upper part of the burden rock is displaced too early, the reduced confinement can result in severe airblast, excessive flyrock, and the formation of toes. Top-of-blasthole priming also favors the creation of backbreak, cutoffs to adjacent blastholes by top rock movement, and potential misfires due to excessive pressure drops for explosives still in the process of reacting. Collar priming should be employed only where instantaneous or very closely timed initiation is present, blastholes are relatively short, vertical uplifting or cratering is required, or where multiple priming is needed.

For small-diameter holes, i.e., those less than 100 mm (4 in.), the primer should be the first charge loaded into a hole. In the larger-diameter blastholes, the primer can be positioned where the most difficult rock to break is located within a bench. Normally where single priming is used, locating the primer at floor level to help reduce ground vibrations will be satisfactory rather than in the subdrill, providing the primer is of adequate size and the explosive in the subdrill is reasonably sensitive. Since it is the opening in the bottom created by subdrilling that provides the stress conditions necessary for the removal of toe, some operators, to reduce ground vibration levels, load no explosive in the subdrill but instead fill it with coarse rock fragments or similar type material. However, the practice requires either a pronounced seam at floor level or a bench height in excess of three times their blasthole burden dimensions.

Multiple priming of a blasthole is required where there are charges separated by stemming, termed deck loading; seamy ground conditions presenting a possibility for cutoffs; and the hole is quite long. In some states, at least two primers are required. The use of deck charges may be needed to reduce the charge quantity fired at any one time so as to

minimize ground vibrations, for economy by decreasing the overall powder factor, and where it is necessary to bypass weak zones such as mud seams (Fig. 14). Each deck charge will require its own primer. In the first case the deck charges employ different initiation time-delay periods. For the other two instances all decks may be fired at or near the same time if the total charge amount is not excessive and initiation is begun at the hole bottom. The exception to initiating the bottom charge first would be where it is necessary for top rock to be lifted or moved first to provide relief for lower decks. If deck loading is used to reduce powder factor only, it is important that deck loads in adjacent blastholes be alternated, or staggered, relative to their respective positions in hole lengths to ensure that explosive distribution is uniform throughout a bench's burden rock.

A long small-diameter hole generally requires multiple primers because it is particularly vulnerable to premature ground movement while its explosive column is still reacting. There are two reasons for this: explosives typically react at slower velocities in small diameters and a hole's burden is small relative to its borehole length, creating a very flexible burden-rock condition. To be certain all the explosive charge will react completely before ground movement occurs, therefore, requires multiple primers to be placed along the charge column, being fired at nearly the same time or at least in a sufficiently rapid sequence before radially cracking is complete and ground movement commences.

To determine the need for primers in addition to the one at a hole's bottom, an estimate can be made by ascertaining the earliest time a crack could propagate from the hole to the nearest open face and comparing that time with that required for the explosive column to completely react. Under most circumstances it can be assumed that the shortest possible distance for any crack to propagate would be the burden as measured from the bottom primer. Since cracks can propagate at the very maximum at a rate of about one-third a rock's sonic velocity, the shortest crack propagation time for a blasthole then would be $3B/v_p$. On the other hand, the minimum time for an explosive column to completely fire would be equal to the powder column length PC divided by the explosive's velocity, or simply PC/v_e . For most situations, therefore, a blasthole's explosive column should be no longer than three times the burden dimension for a single primer located at its hole bottom. If high velocity explosives are used in low sonic-velocity rock, longer powder columns could be used without additional primers located higher in the explosive column, the reversed condition requiring shorter column lengths. As a means for estimating the maximum length of explosive charge PC_{max} for any single primer, the following expression will be appropriate:

$$PC_{max} = 3B(v_e/v_p). \quad (7)$$

Where the actual explosive column exceeds the PC_{max} value, the additional required primers should be spaced equidistant along the column as may be appropriate. For example, considering a 75-mm (3-in.) diameter blasthole with a 1.83-m (6-ft) burden, an 11.6-m (38-ft) powder column, and a v_e/v_p ratio of 0.6 so that PC_{max} would be 3.24 m (10.6 ft), a total of 3.58 or 4 primers would be recommended, spaced 2.9 m (9.5 ft) apart beginning with the bottom primer.

Multiple Hole Design Principles

The typical blasting round consists of a number of blastholes arranged in one or more rows of holes in such a way that certain specific requirements will be satisfied. As a rule, the arrangement will be designed to produce a given mini-

mum tonnage or volume of broken ore or rock, the in-place bench height and area of which will have their respective dimensions more or less limited because of restrictions imposed by the equipment used to load or strip the broken material. To produce the necessary volume of rock, the blasts will be one of three possible forms: the sinking cut for initially opening an area, the box or trenching cut for extending an excavation lengthwise, and the corner cut (Fig. 6). Once a bench has been established most cuts will be of the corner type until such time as a new opening will have to be developed. Regardless of the cut type, however, the same principles upon which to design an appropriate drill round will always apply.

There are three rules for locating drill holes that should be followed in every case when designing a blast: (1) tight conditions should be avoided whenever possible with adequate space provided for each hole to account for swell, (2) the proper burden should exist for each and every blasthole at the time it fires, and (3) holes should be positioned so the radial cracking and flexural rupturing processes will not be impeded. Insofar as practical, holes should also be aligned with the rock's joint planes and particularly so the perimeter holes of the blasted area ensure clean breaklines at the edges. In addition, a round's cut holes, i.e., the first blastholes to fire, must be properly located so they will provide the necessary relief for all subsequently fired blastholes.

Equally important to the burden and hole depth dimensions is the charge spacing in a blast's design. The spacing dimension S is defined as the distance between any two adjacent blastholes, measured perpendicular to their burdens. The spacing in conjunction with the firing times of adjacent charges and the rock's structural discontinuities provide the primary means for controlling whether or not the holes will interact during a blast. Where the spacing dimension is not compatible with the timing and rock character, the fragmentation and the control over detrimental side effects will be affected. For example, too wide a spacing produces poor breakage, toes, and humps on faces between holes. Too close a spacing generates excessive fracturing and collar cratering between holes, blocky burden rock, and toes. Airblast and flyrock frequently occur also under such a condition. In selecting a spacing it is most important, therefore, that one first consider the probable directions radial cracks will follow, any possible interactions that may occur between holes in any direction, and the general overall stiffness conditions of the burden and collar rocks of the neighboring blastholes at the respective times they are intended to be fired.

For design purposes, it is common to consider the spacing in terms of the burden on a blasthole in the form of a ratio. For most situations the S/B ratio's value will be from 1 to 2; although in certain instances where conditions are favorable, larger ratios have been used with satisfactory results. In general, blastholes fired independent of one another will require a spacing ratio between 1 and 1.5, a 1.41 value being the ideal geometric balance for breakage of massive material. For rocks with joint planes located nearly perpendicular to one another, the following first approximation for independently fired holes will be applicable:

$$S = 1.41B. \quad (8a)$$

Where a rock's joint planes are oriented at close to 60° with one another, blastholes with long-delay interval firing times generally require closer spacings as given by the following relationship:

$$S = 1.15B. \quad (8b)$$

Fig. 17. Plan view of angled corner cut with staggered pattern for echelon independent delay firing.

Minor adjustments to the spacing should be made if the overall fragmentation achieved and general appearances of the bench faces remaining after blasting are not satisfactory. However, modifications in the spacing cannot be expected to compensate for an extremely stiff burden rock condition, e.g., a B/L ratio that exceeds 0.5 in value. Figs. 17 and 18 provide a comparison of two three-row corner cut designs in which holes are timed to fire separately using the spacing relationships given previously. In the diagrams it should be noted that the individual areas of rock broken out in their respective diameter planes are well balanced with uniform burdens to their side faces at the time each fires. Also, in conformance with crater form IV given on Fig. 10, the re-

Fig. 18. Plan view of angled corner cut with staggered pattern for echelon independent delay firing modified for 60° degree rock jointing.

spective burden rocks can be moved out easily as a consequence of their characteristic wide crater-apex angles.

For blastholes fired at close interval timings or simultaneously so interactions can occur between adjacent holes, the spacings must be extended to produce uniform breakage with a minimum of detrimental effects. Otherwise, radial cracks from borehole sides will join prematurely before breakage by bending out of the solid can develop. For a sufficiently large enough bench height, i.e., the B/L ratio is less than 0.5, ideal geometric balancing between charges will exist where the spacing dimension is double that of the common burden. However, field experience and laboratory tests on models show that as burdens are increased for a given bench height, spacings must be reduced to compensate for the stiffening of the burden rock where burdens are larger than one-third the bench height. The effect is apparently geometrically controlled and independent of the rock type. The similarity of trends is illustrated by Fig. 19, which shows the maximum permitted S/B values at various L/B ratios for complete shearing between holes obtained from tests conducted on models of three completely different materials. On the basis of field data and laboratory test results, the relationship for approximating charge spacing for blastholes fired closely together with hole depths three or less times their burdens would be the following:

$$S = (BH)^{1/2} \quad (9)$$

In those situations where H is more than three times the value of B for blastholes fired at close time intervals, or more or less together, the S dimension of $2B$ usually will be satisfactory. For rock conditions under which it is difficult to break cleanly between holes, a slightly reduced spacing to about $1.8B$ generally is quite sufficient.

Two basic blast designs in which holes in the same row are fired at the same time are illustrated in Figs. 20 and 21, one pattern being arranged with displacement of the broken material directed at any angle into the pit area opposite the bench corner, the other being designed to spread the broken rock uniformly out in the pit parallel with the bench's length. It should be noted, however, that there is slightly more bench area broken by the latter of the two patterns in spite of the

Fig. 19. Relationships between S/B and L/B design ratios for close-interval delay firing.

Fig. 20. Plan view of angled corner cut with square pattern for echelon close-interval delay firing.

fact both arrangements contain twelve holes each, burdens are constant for all holes when they fire, and the respective spacings are correct for the initiation timing system employed. On the other hand, the latter pattern is subject to causing overbreak at the end of each hole row while the design using delayed firing times in rows paralleling the bench length or w direction will be devoid of endbreak. The reason for this difference is that the extended length of open face beyond an end hole's location of a series of holes fired together creates a condition by which the composite burden rock for a row will function in a manner similar to a cantilever wide-beam or plate. The action is often clearly visible when such a blast is in progress. To avoid the problem, it is always

Fig. 21. Plan view of angled corner cut with staggered pattern for frontal close-interval delay firing.

Fig. 22. Plan view of V-cut with square pattern for close-interval delay firing.

best to delay the firing of the last hole in a row until the neighboring hole in that row has been fired and most of its burden rock has been moved out of its place. The spacing for the last hole should also be reduced as for any independently fired blasthole.

There are only two basic types of drill patterns: the square and the staggered arrangements. The distinction between the two depends on how the orientation of hole rows is defined. For corner cuts, the alignments of holes paralleling a bench's length, or w dimension, are considered as the rows (Figs. 20 and 21). For the sinking and box cuts, the rows normally would be the lines of holes paralleling the cut's longest dimension. The square pattern will be where holes in rows are positioned directly behind one another with equal distances between holes in rows and between rows (Figs. 20 and 22). For square patterns to give satisfactory results, however, hole depths should be at least three or more times hole burdens, adjacent holes in the same row must be delayed relative to one another, and holes located laterally in adjacent rows should be fired together. In the staggered pattern, the holes in one row are positioned in the middle of the spacings of holes in adjacent rows. The square pattern becomes a staggered pattern if the initiation delay-timing system is rotated 45° from its initial position. Where holes fired together cannot have their spacing at double their true burden and where adjacent holes must be independently delayed relative to one another, either the rectangular or staggered pattern is required. The rectangular design is normally applicable only for box cuts in which the holes are delayed as shown in the example in Fig. 23.

Although rectangular and square patterns are easy to lay out for drilling, a corner cut using either a square or rectangular shaped area is not usually satisfactory. This is because the square block of burden rock on the open corner is virtually impossible to break properly due to its shape (Fig. 24), and the last hole in the front row of holes with such patterns quite often tends to overbreak. To avoid the prob-

Fig. 23. Plan view of V-cut with rectangular pattern for independent delay firing.

lems, the two side faces for corner cuts are best situated when angled with one another. For the opening box cut to develop angled bench faces, the square pattern can be employed if hole depths are sufficiently long enough compared to their burdens and only those holes fired together laterally from the front of the cut to its back are used. Otherwise, a stag-

Fig. 24. Plan view of square corner cut with square pattern for echelon close-interval delay firing.

gered pattern with holes on row ends delayed most often is applicable, as illustrated in Fig. 25.

Equally important with the use of proper burdens, spacings, and hole depths is the selection of a compatible initiation delay-time pattern for the various explosive charges. Three time elements should be considered for each blasthole: (1) the time t_m for the burden rock to first begin its initial movement at the primer location, (2) the time t_r required for the explosive in the hole to react completely, and (3) the time t_b for all of the broken material to move out at least one full burden distance. For any two holes to be fired independently so no interactions are possible between them, then the total minimum delay time in their respective firings should be no less than the sum of the three time elements, or $t_d = t_m + t_r + t_b$. The move-out time is particularly critical for certain kinds of blasts, especially from the standpoints of controlling toe formation, overbreak, and potential violence caused by tight conditions.

A common rule for t_m is to assume that rock movement begins approximately 3.28 milliseconds for each meter of burden (1 ms/ft) after the primer's initiation, and broken rock can be considered to move out from faces at an average rate of about 23 m/s (75 ft/s). The time required for an explosive column to react t_r would be its length PC divided by the explosive's v_e . Therefore, to determine the minimum delay-time interval in seconds for independent firing of blastholes, the following approximation can be used:

$$t_d = B/305 + PC/v_e + B/23, \text{ sec.} \quad (10a)$$

in which B and PC are in meters and v_e is in m/s. If B and PC are measured in feet and v_e is in ft/s, the relationship would be

$$t_d = B/1000 + PC/v_e + B/75, \text{ sec.} \quad (10b)$$

For example, to avoid all possible interactions between two neighboring bottom-primed blastholes with 3-m (10-ft) burdens, 9.14-m (30-ft) powder columns, and containing explosives that react at 3050 m/s (10,000 ft/s), the estimated required minimum delay-time interval in their respective firings would be 143 ms. On the other hand, the full face of burden rock would start its initial movement outward in an estimated time lapse from initial firing of approximately 13 ms, or the sum of only t_m and t_r . Any time interval of delay firing used for initiating the second blasthole greater than 13 ms but less than 143 ms following firing of the first hole,

Fig. 25. Plan view of opening box cut using independent and close-interval delay firings arranged to avoid overbreak.

therefore, could be expected to produce interactions in the ground from the two holes.

Rock breakage enhancement effects from the use of millisecond delay initiation has been observed for many years. The effects result from strong shearing stresses developed by the differential displacements generated in the ground where borehole pressures from adjacent blastholes are applied while the respective burden rocks are still under pressure loadings. Mutual stress-wave interactions seldom if ever would be possible in normal field blasting due to the delay time-lapse intervals involved and the characteristic rapid propagation rates of such waves. For example, under the situation given above, stress waves would have developed and propagated away from the first hole in ground having a sonic velocity of 3000 m/s (9840 ft/s), a distance equal to about ten burdens in the three 13-ms time interval preceding any firing of the second blasthole. Figs. 26 and 27, produced by computer simulation using the finite element analysis technique, illustrate the differences in ground stressing conditions in the charge diameter plane for two delay-fired blastholes spaced at double their burden values and aligned with a dominant joint plane orientation. Comparing the two plots, the shearing interaction effects generated by the holes fired at close-in-

Fig. 26. Maximum principal stress contours produced by fired corner hole with pressurized crack developed along joint plane but adjacent second hole not fired.

Fig. 27. Maximum principal stress contours produced by two fired adjacent holes at close-interval delay timing.

terval delay timing can be readily distinguished. Because fractures tend to follow directions perpendicular to principal stress contours the need for using closer spacings in the case of independently fired blastholes is also indicated, considering the conditions as shown in Fig. 26.

The use of proper delay timing not only promotes good fragmentation and displacement results but also can minimize external blast effects such as airblast, flyrock, and ground vibration. Airblast, for example, can result when the displacement rate of ground during blasting exceeds the sonic velocity of air, or 335.3 m/s (1100 ft/s) at sea level. The generation of an overpressure occurs much like the piston-like compression effect that propagates a shock front similar to the sonic boom generated by aircraft. The problem develops where very long length-to-diameter charges react at high rates, or too close a timing between holes in a row causes a strong composite overpressure when airblast pulses generated by individual charges superimpose on one another. Adequate delay time is similarly required between hole rows so there is sufficient relief to avoid reinforcement effects of airblast and ground vibration.

Several guidelines have been developed to aid blasters in the selection of delay time intervals that will provide suitable

fragmentation while keeping airblast and ground vibration at controllable levels. The rules are as follows:

1. The minimum delay time interval between holes in the same row should exceed 3.28 ms/m of burden (1 ms/ft) with an upper limit of 16.4 ms/m (5 ms/ft) to achieve good fragmentation in massive rock;
2. The delay time interval between rows of holes should be two to three times the delay used between holes in a row;
3. The rate of blast propagation along an open face should be less than the sonic velocity for air, i.e., 335.3 m/s (1100 ft/s) and preferably half that value where possible but at least 7 ms/m of spacing (2 ms/ft) to prevent airblast from superposition; and
4. The minimum delay time interval between adjacent charges, whether between holes in a row or between rows, or between deck charges in a single hole, should be at least equal to the nominal delay intervals of the delays used to control ground vibration.

To calculate the rate of blast progression along a free face to control airblast, the spacing distance between holes simply needs to be divided by the delay time interval used. For example, if the spacing between holes in a row for the blastholes described earlier were 5.5 m (18 ft) and the delay time interval were 50 ms, the rate of blast progression would be 110 m/s (361 ft/s) or only about one-third the sonic velocity for air, thus presenting no problem. With that particular delay interval, also, there would be rock breakage enhancement between adjacent holes because for completely independent firing a delay time of some 143 ms or more would be required between the firings.

Most regulatory authorities consider two charges fired at delay time intervals of 9 ms or more as two separate firings

as far as controlling ground vibration is concerned. Few blasting rounds, regardless of the number of charges and their locations, present a delay timing problem since the introduction of the sequential timing blasting machine. Where surface delays and sequential timers are employed, however, in-hole delays are also recommended so as to reduce the possibility of cutoffs that might occur due to early ground movements.

Powder factor is not normally a sound index upon which to design blasts. The powder factor relates the yield of material blasted to the quantity of explosive used and will be extremely variable for the different types of rounds, explosive-rock combinations, and burden, spacing, and bench height conditions. Higher energy explosives, for example, can break more rock than can lower energy products, and box cuts provide lower amounts of broken material than do corner cuts using the same blasting design relationships. Comparing Figs. 17, 18, and 20 through 23, one will observe that not only can powder factors vary between cut types but also will differ for the same basic kind of cut depending on the particular delay-timing arrangement used. For surface blasting powder factors can vary from as low as 0.15 to as much as 1.5 kg/m³ (0.25 to 2.5 lb/yd³), with 0.3 to 0.6 kg/m³ (0.5 to 1.0 lb/yd³) being the most typical. On a yield weight to explosive used weight basis powder factors could vary from 3.4 t/kg to 13.5 t/kg (1.7 to 6.8 st/lb), depending on the materials blasted, explosives used, and kind of fragmentation desired. In general, for most blasting in construction and mining, the factors will range between 4.8 and 7.6 t/kg (2.4 to 3.8 st/lb). However, other than determining the powder factor for cost purposes, its use as a basis upon which to design blasts is not recommended.

6.3 Overburden Removal

GEORGE E. AIKEN
JOHN W. GUNNETT

GENERAL OVERVIEW

Any evaluation of a specific need for overburden removal requires that the engineer first be aware of the various designations of overburden, the state-of-the-art removal systems, and methods to transport these materials to permanent deposition areas.

When concerned with the development of a mine, the overburden removal system should be in harmony with the mine planning of the future. Unless this and the other factors influenced by overburden removal schemes are carefully considered, operations may suffer in efficiency and costs.

This section examines the definition of overburden, the tools to remove it, and the transport methods available for moving it to disposal sites. Table 1 is a generalized guide to excavating and transport methods that may be used for overburden removal, and Table 2 is a similar table more oriented to surface coal mining.

Overburden Defined

Depending on the user, the term overburden can be defined in several senses. For the miner, overburden is used in the context of any material, loose or consolidated, lying over a mineral deposit of ore or coal. This applies especially to surface mine operations.

To the builder, civil engineer, or soils technician, the term can refer to only loose soil, sand, or gravel that lies above the bedrock. The term should be well defined then as to the type of material(s) that are being considered to design for the most effective removal method. Having defined the overburden type, the excavation tools may be assessed.

Excavation Techniques

These are, for all practical purposes, limited to the presently produced production mining equipment. A discussion

of each of the potential machines can be found in a later section. The most common machines in everyday use are: draglines, power shovels, dozer/front-end loaders, dredges, motor scrapers, and bucket wheel excavators (BWEs).

Occurrences: Excavator selection should be well suited to the type of overburden occurrence. This will involve consideration of depth of material, hardness, abrasiveness, moisture, suboverburden topography, waste dump sites, ore overburden interfaces, and surface topography.

Engineering studies to select optimum methods must ensure that the machines can efficiently cope with the conditions to be encountered. Where alternate choices may be possible, it may be necessary to carry out detailed comparative cost analyses studies.

General Techniques: In most instances the overburden is removed only far enough ahead of mining to ensure an adequate ore supply. However, the entire operation of overburden removal must be examined from the standpoint of project requirements. Where backfill for construction may be in short supply, the overburden stripping operation may need to be accelerated. Other factors that may affect the overburden removal techniques are the need for road construction, tailings, and water retention dams.

Consideration should be given to the multiple use of construction earthmoving equipment in the overburden removal scheme. Providing economically acceptable and compatible equipment may be selected, the overall costs can be reduced and double handling the material may be avoided. It is not uncommon to find that this equipment is fully depreciated at the start-up of production. This may allow the mine the chance to select different equipment that could be more advantageous for overburden only.

Another technique which some owners may find eco-

nominally convenient is the use of contract stripping. This relieves the owner of any need for capital expenditures over the preproduction/construction period. Contract stripping can even be continued into the production years if economically rewarding for both owner and contractor.

With widely dispersed, smaller deposits, the excavator units need to be of small capacity and highly mobile. One or two large machines may be inappropriate due to their lack of selectivity between ore and overburden or their need for frequent moving about to work multiple faces.

Topographic conditions must be suitable for the selected excavator. Very steep, mountainous areas usually call for benching using shovel or front-end loader type excavators. Gentle to moderately sloping conditions often are more favorable to the dragline or bucket wheel excavator (BWE). Dozing and front-end loader combinations may be applicable over a wide range of topographic conditions.

Where the overburden is hard and must be blasted, the excavator should be able to efficiently and economically load the blasted rock chunks. In very soft overburden, the excavator must be supported as it moves across the area to be stripped. This will require a machine having low unit bearing pressures. These and other special problems of the excavator are discussed in the section on Overburden Excavation.

Overburden Relationships: Closely related to the quantity of overburden to be excavated is the relationship to pit development. Enough overburden has to be stripped back to allow the planned sequential development of the mine. Depending on depth of overburden, mine scheduling, disposal space availability, weather conditions, material stability, and cost relationships, the rate and method of waste excavation will be factors in sizing equipment.

Since overburden has already been defined as the capping on the mineral reserve, the excavation rate must be related to a designed stripping ratio. This is a parameter universally used in surface mining operations. The interpretation is not always the same and the term should be carefully defined to apply to a specific mine or condition. For example, it is quite different in the coal industry where it refers to the cubic yards (bank) of overburden removed per ton of coal mined.

However, in hard rock mining to define the stripping ratio in the example of Fig. 1, consider mining of the ore ABC at depth h . Having defined the slope angle at this mine section, the waste (overburden) section AICD must be removed. The ratio of this overburden stripped to mine the ore is known as the average stripping ratio (SR).

$$SR = \frac{\text{Volume waste at depth } h}{\text{Volume of ore at depth } h} = \frac{AICD}{ABC}$$

Thus SR can be shown to be a geometrical relationship. It can be noted in Fig. 1 that initially the overburden stripping ratio will have a theoretical value equal to infinity, e.g., no ore is recovered. In the case illustrated, when the first ore is mined the value of the average stripping ratio will have its highest value. This will decrease as the ore recovered increases with depth and will reach a minimum at some point. The average stripping ratio will begin to increase again as the open pit volume increases and the pit becomes deeper.

A ratio of the incremental amount of overburden to an incremental amount of ore is defined as the *incremental stripping ratio*, or SR. This is illustrated in Fig. 1 where the incremental volume of overburden CDEF must be removed to recover the increment of ore at depth h_1 , or area BCFG.

$$SR = \frac{\text{Volume of incremental waste at depth } h_1}{\text{Volume of incremental ore at depth } h_1} = \frac{CDEF}{CBFG}$$

This relationship is also geometric, but using economic parameters the maximum incremental overburden removal ratio can be calculated. This maximum ratio will define the ultimate overburden to ore ratio or pit limit. At this point the value of the recovered mineral pays the costs of mining, overburden removal, beneficiation, and a minimum acceptable profit.

Fig. 1 assumes a homogeneous ore body, but if waste strata or large horsts occur that must be selectively removed during mining, these volumes will be additive to the overburden increasing the SR. Therefore, the amount of overburden that may be economically removable to reach ore may be decreased and reduce the amount of recoverable ore. Thus when the incremental stripping ratio exceeds the economic stripping ratio, open pit or surface mining ceases to be profitable.

Transport Systems

The excavated overburden must be transported to a deposition site. Economics dictate that the transport distance be as short as possible, consistent with the mine plan, and any other special requirements, such as the eventual rehabilitation of the mined area or other environmental concerns.

Selection of the transport method should be analyzed. This will ensure a system of optimum cost and one most suitable to the characteristics of the material to be moved.

Material Characteristics: Depending on the nature of the material to be transported, there may be either a very limited choice of equipment or a wide selection. See the chart of equipment choices matched to equipment types, Fig. 1. There are more alternates to select from for handling consolidated materials than for soft, water-saturated materials.

Fig. 1 Stripping ratios.

This transport system should also be selected to suitably take other aspects into consideration such as material size, degradation, hardness, and abrasiveness.

Equipment Review: Once the significant parameters of material characteristics are defined, equipment for transporting the material may be reviewed. Generally, several methods of transportation will be found to be feasible. Technical evaluation will limit these several feasible methods, as a rule, to two or three most likely to be appropriate.

Some of the technical aspects that may be limiting factors are the production level demanded, the equipment capital cost vs. operation life, the length and elevation difference of the transport route, any special requirements in placing material in the dump, and others.

As an example, a small operation with a short life will not likely be able to support either a railroad or expensive overland belt conveyor. The small operator will select low capital cost mobile transport of trucks or scrapers. Economy of size becomes apparent when dealing with very large production tonnages. These are the operations that will support long depreciation periods for expensive high technology systems with their potential for minimum operating costs.

Mine Compatibility: Most operators agree that interchangeability of pit equipment is good. Therefore, if possible, consider similar transport equipment for both overburden and ore. This offers the advantage of a smaller parts inventory, a narrower range of maintenance requirements, and a resulting lower operating cost.

Environmental Concerns: Disposal of overburden may often involve issues of environmental concern. Some of these are visual and others may be related to the discharge of noxious or hazardous materials.

Where overburden must be dumped in sites at some distance from the mine, the visual aspect of the dumps may have to be considered. To present dumps as visually attractive to viewers may require contouring, and seeding or foresting to harmonize with the surrounding country.

The mineral content of the dumps should be well known. This will provide information as to the steps that must be taken to contain leached solutions. When these are allowed to escape freely without neutralization, severe damage may occur to the immediate quality of life including stream pollution and damage to plant or animal life.

Runoff waters from leached overburden dumps may be a possible contaminant to subsurface aquifers. These frequently feed to more distant sources of human water supplies. To avoid this potential hazard requires a good knowledge of the local geology, e.g., fissures, faults, and local hydrogeology.

An increasing concern for protection of the environment during mining and recent enactment of stringent mining regulations mandate that the mine operator give extra thought to the environmental planning process. However, by incorporating basic principles into any mining technique, high productivity with little environmental disturbance can be achieved. Principles include:

- 1) Practice spoil segregation and immediate burial of toxic material. (Topsoil comes in A, B, and C layers, each of which must be segregated under certain regulatory requirements.)

- 2) Where topsoil is of sufficient quantity and reasonable quality, remove and reapply on regraded spoils in one operation, if possible.

- 3) Incorporate as many production operations as possible into reclamation procedures, thus integrating unit operations.

- 4) Have a preplanned reclamation scheme which can easily be integrated with a feasible mining plan.

OVERBURDEN MATERIALS

Overburden, as discussed here, will refer to the first referenced definition as stated in the section, Overburden Defined. Thus any material lying over an ore or coal deposit is defined as overburden. The approach to its removal will depend on the material characteristics. Commonly encountered types of material are: topsoil, soft overburden, medium hard rock, and hard rock.

Topsoil

This is a general term applied to the near surface portion of the material lying above the ore. Topsoil has sufficient agricultural nutrients to support varying degrees of vegetation growth. This layer or layers of soil may only be a few inches deep or extend to several feet in depth.

In recent times its segregation in the removal stage may have prime importance. This has occurred from the impact of governmental regulations for replacing topsoil as it originally existed on mined areas. To do this requires that each layer be carefully excavated and placed in an area where relatively easy recovery can be made. When replacement is required, topsoil should not be mixed with the agriculturally poor underlying materials.

Topsoil Characteristics: In addition to the agricultural attributes of topsoil, it is an unconsolidated material. It is frequently loose and plastic in nature. The water content may vary, and mineralogically it may contain clays, sand, fully decomposed rock, loess, marine remnants or combinations of these.

Where topsoil exists and must be removed, it may be necessary to call on qualified soils experts to accurately define the topsoil. This could be the case where topsoil grades gradually into a relatively poor agricultural material. The latter may be a soft or decomposed rock from which the topsoil originated.

Soft Overburden

This may either be gradational downward from the topsoil interface or be the primary material on top of the ore. Typically it might be a glacial moraine of unsorted material, a rock advanced in decomposition but with original structure, agriculturally poor sands, barren or marginal grade laterites, clays, or other soft material that is not classed as topsoil.

Under certain circumstances part or all of these materials may be stockpiled separately for later land rehabilitation. Some soft overburdens not considered as topsoil, with an addition of nutrients, may make a soil capable of supporting vegetation cover. This can be done to retain recontoured land, minimize erosion, and ultimately improve the original land condition.

Excavation of soft overburden can be done for a minimum cost; separate dump locations may not be required. Frequently the soft overburden goes to the main waste dumps without segregation. Soft overburden may also be useful as road ballast.

Soft overburden normally can be excavated without drilling and blasting. Equipment typically used for the soft in situ material, either dry or with a high water content, is indicated in Tables 1 and 2.

Medium Hard

This classification covers a wide range of rock types. It includes most semi-decomposed rock, highly fractured or well jointed rock systems, shales and schists with easily rup-

tured parting planes, many cemented conglomerates, and other rocks that can be broken for loading with moderate forces.

Rock breakage may be done using drilling and light blasting, ripping by a dozer, fracturing and breaking with a dozer blade, or in a few cases by the milling action of a bucket wheel excavator (BWE).

Overburden of medium hardness is normally of no value for agricultural purposes, but it may be used as a base for returning mined areas to the original topographic contours. Where rock overburden has been stripped from an open pit operation, it is unlikely that it would be used to fill the pit after mining is finished. The most likely environmental solution would be to reshape and contour waste dumps, adding an adequate cover of topsoil if required, and planting some form of vegetation adaptable to the conditions. The abandoned open pit would most likely fill with water becoming a lake in a potential recreation site. The final disposition of harder rock overburden is similar to the medium hard.

Hard: Drill and Blast

This is overburden that must be drilled and blasted before it can be dug and loaded. It may occur from the surface to the ore interface or lie at some depth below the surface. In most cases the hard overburden is the barren country rock surrounding the ore body. Fig. 17 shows the relationship of a typical hard rock overburden to the ore zone.

Equipment for excavating and transporting the hard rock must be robust to survive the impacts of loading and abrasion wear. The principal machines used are the power shovel, dragline, and hydraulic shovel. Smaller operations will often use the rubber tired front-end loader; but for sustained, long-term loading of hard rock, the shovel and dragline are preferred.

Where draglines or direct casting shovels are used, the blasted rock is usually side cast to disposal and end dump trucks will work with power shovels. In some cases where the broken rock is used for civil construction, the transport system is automatically defined. In recent years, with fuel- and cost-conscious planning influencing mine layouts, interest is widespread in crushing rock waste in the pit and moving it by belt conveyor. Having established the character of the overburden material, the choice of the excavator can be made.

OVERBURDEN EXCAVATION

Most of the major methods for excavating the overburden are cyclical in nature. This means that they experience interruptions in the digging and material-moving elements of the operation. The important exceptions to this are dredges and the bucket wheel excavator. Each of the major overburden excavators is discussed here from the standpoints of method of application, suitable material for handling, machine characteristics, support functions required, and selection criteria.

Dozers / Front-End Loaders

Dozers or pusher-type tractors are either mounted on crawlers or on rubber tired wheels. Rubber-tired dozers have little application to overburden removal when working alone. Crawler-type tractor dozers are frequently found working alone pushing loose or blasted overburden in preproduction benching operations.

Tractor push blades are available in a variety of designs for different applications. The range of the hardness of the material handled by the crawler dozer may be very large. A crawler tractor's pushing ability is only limited by the machine weight and horsepower. This is also true for the rubber-

Table 3. Characteristics of Rubber Tired and Track Type Dozers

Dozer Type	Horsepower	Approx. Weight (Dozer Only) St	Capacity Loose cu yd per hr
Track	180	18.2	458
	270	29	628
	385	40	889
Rubber-Tired	300	32	366
	400	41	562

Metric equivalents: hp \times 0.746 = kW; st \times 0.91 = t; cu yd \times 0.765 = m³.

tired dozer, but under most conditions of overburden removal where a machine works unassisted, the crawler dozer is preferred. It generally takes a heavier rubber-tired dozer to exert a given push force than it does a crawler tractor, due to the greater coefficient of friction for the crawler-type dozer (Shand, 1970). Table 3 illustrates this relationship within a 30 m (100 ft) push distance. The rubber-tired dozer is more often found as a secondary cleanup machine working with a loader or other overburden excavators especially where mobility is necessary.

Front-end loaders are either crawler- or wheel-mounted. The latter is used almost exclusively in surface mining because of its mobility. The front-end loader is primarily used for loading trucks, however, where the overburden deposition distance is relatively short, a load-and-haul type operation may be employed. It is common to find the track dozer working with the wheeled front-end loader. Where the hauls are short, the wheeled dozer works well from a stockpile as

Fig. 2. Generalized production comparison for front-end loaders vs. bulldozers.

a load-haul-dump machine, the stockpile material being excavated and pushed into a pile by the track dozer.

Fig. 2 shows the effect of distance on dozer and front-end loader production. As a general rule of thumb, dozer push distances should be maintained at less than 61 to 76 m (200 to 250 ft) while front-end loader tram distance should not exceed 152 m (500 ft) with 91 m (300 ft) being a more desirable limitation for economic production.

The types of overburden that can be dozed are loose and/or friable. Typically a dozer may be used to move a topsoil layer downslope from a hillside benching operation. Crawler dozers are frequently used during mine development for moving shot rock overburden. In preproduction this may involve opening the initial mine benches by dozing the blasted rock over the edge of a steep decline. Gravity carries the dozed rock down the hillside and under optimum conditions no further handling is required.

Overburden removal by ripping and dozing has increased in surface mining with the advent of the larger machines. Tandem ripping, adding the weight and power of a second tractor, will further expand the rippability range (Jackson, 1979). However, the costs of ripping must be evaluated against the resulting higher repair costs. Costs of 120 to 130% of the depreciation for repairs are not unusual (Jackson, 1979). Production ripping, where feasible, can loosen material for one-third to one-half the cost of drilling and blasting. Light blasting with ripping can also be, in some cases, cost effective. Seismic refraction tests help to determine the degree of rock rippability. Fig. 3 shows the potential performance of a Caterpillar D10 tractor.

Dozers/Trap Loaders (Belt Loaders): Trap loading operations are traditionally associated with earthmoving contractors. Since the mining industry is generally unfamiliar with the equipment, its application in suitable material has

been limited. A few mining operations have used trap loaders or belt loaders with great success. One of the most remarkable applications was the use of the trap loader and shiftable conveyor belt transport system for soft ore from a South American iron ore deposit (Anon., 1975). A sand and gravel operation also uses the belt loader/shiftable conveyor system in California.

Belt or trap loaders are heavy duty units made up of a material-receiving box or trap and a discharge conveyor belt. Design variations are possible that permit loading by dozers, front-end loaders, or even rubber-tired scrapers. Material can be dozed to the loading station from 61 to 91 m (200 to 300 ft) away. Two or more stations may be operating with stations being leapfrogged to maintain production.

Scrapers

Although the scraper has been around since the early 1930s, the machine is relatively new in surface mining. In the 1970s it became a proven tool for stripping overburden. Because of its excellent mobility, low initial cost, and sturdy construction, the scraper will continue to have widespread application.

Scrapers can be classified into four general types: (1) tandem-powered; (2) push-pull; (3) single engine; and (4) elevating.

The tandem-powered machine is preferred for steep grades and poorer underfoot conditions with the front and rear engines providing the traction needed. Push-pull scrapers are combined in a "buddy" system that can self-load each scraper. On the travel leg, they separate from their special loading hitches to move independently. The single engine machine requires a pusher dozer and will perform well for removing thin lifts, mixing soils, or special grading.

Synchronized teams of scrapers and dozers can econom-

Fig. 3. Caterpillar D10 ripper performance vs. seismic velocity. Performance estimated by seismic wave velocities. Multiple or single shank No. 10 ripper. Production shown for 14 rippers.

ically remove overburden 20 m (65 ft) or more in depth (Chironis, 1979).

Frequently, the scraper may be used in combination with other mining machines. As an example, the early use of scrapers, during the delivery period of the main excavators, may allow the mine to reach full production at an earlier date. Scrapers may also remove an upper level of overburden, eliminating the need for any dragline rehandle.

The Lucky Mc mine in Wyoming is believed to be the first mine to use scrapers for overburden removal (Anon., 1969). Since then scrapers have been used to move a wide range of overburden types. In Arizona at the Twin Buttes mine, 140 m (460 ft) of overburden was moved by a scraper belt conveyor system. Other mines using scrapers for overburden include phosphate, uranium, aggregate, coal, iron, and copper.

Draglines

There are three types of draglines: (1) truck-mounted, (2) crawler-mounted, and (3) walking.

For overburden removal, it is necessary to consider only the crawler and walking machines since the truck-mounted machines are small in capacity and are not designed for overburden removal work.

Some years ago a dragline was considered to be a trans-

porter rather than a production tool. It moved material over fairly long distances while machine moving speed and production output were not much considered. The dragline's prime purpose was to transport material out of the way of mining. Today the dragline is an important production tool designed to move large volumes requiring increased power and speed of bucket movements. Longer dragline booms have increased the possible transport distance and the working range of the machine.

Dragline usage has outpaced shovel applications in a large percentage of the overburden removal work. Where conditions of pit design can take advantage of the reach and dumping radius of the dragline, much deeper overburden can be removed for less cost than with shovels and trucks.

The dragline is versatile and easily maneuvered from a top-digging position as opposed to a shovel in a pit situation. Bank or bench failures that may be catastrophic for other pit equipment seldom impede dragline operations.

Topographic variations at the overburden-ore interface are easily adjusted for in dragline operations. Overall planning can correct for digging variations of a localized nature by a change in cut width. In some cases draglines must remove material from a bench above the working floor to allow a single machine to handle the full depth of overburden. This is usually not as efficient as the standard operation, but

Fig. 4. Extended bench modified area mining with rehandle.

may be more cost effective than additional machines for the top bench material. The operation of working a face above the machine support level is called chopping.

Draglines will handle a wide range of materials, both in situ and shot rock. Fragmentation of rock must be suitable in character for the dragline bucket size selected. Shovels will be less affected in productivity by large blocky material, and a shovel tends to have a higher loading factor than a similar size drag bucket.

Draglines will permit a higher percentage of coal recovery than a shovel, although the dragline will require closer supervision. The dragline has a lower maintenance cost than does a shovel.

Draglines are ideally suited to the deep overburden so frequently encountered today. However, applications studies should be carried out to determine the optimum scheme. In the case of upper overburden removal (chopping), combinations of equipment working with the dragline must be considered where rehandle becomes a significant factor in productivity.

Some of the possible alternative combinations with dragline operations are dozers, scrapers/dozers, shovels/trucks, front-end loaders/trucks, BWE/conveyors, shovels/cross pit conveyors, and shovels/around-pit conveyors.

One possible way to reduce the dragline size is to bench ahead with dozers pushing a lift of overburden into the pit. The dragline then might work from an extended bench and rehandle the prestripped material, as illustrated by the artist's drawing in Fig. 4 and the schematic drawing in Fig. 5. The other alternatives also involve removing the upper overburden, but transporting it independently of the dragline work.

Before deciding to employ the extended bench mining method, the operator should calculate the rehandle volume and determine the added cost and production decline. Comparative evaluations with alternative mining systems and/or equipment purchases lead to the most cost effective decision. Many operators are forced to make the best possible use of existing equipment, and the extended bench method may afford a technically viable means of extending the dragline digging depth. Several factors are considered in determining the volume of rehandle. First is the angle of repose in which material will naturally set if not compacted or disturbed. In an area mine where no rehandle is normally experienced, this angle is formed by the material after the dragline disposes of it in the adjacent cut.

The second factor is the highwall angle or slope of the highwall exposed in excavation. The third is the cutback angle not normally recognized in calculations. In Fig. 6 this is the angle the material will form when the dragline is excavating the extended bench. With conventional spoil material consisting of shales and sandstone, the cutback angle usually runs between 50° to 60°. This is much shallower than

Fig. 5. Schematic of extended bench method.

a highwall angle of 75° to 85°. Table 4 indicates the basic method of recalculating this area of rehandle.

Other methods can be used in the field to determine the rehandle percentage more accurately than by using the formula depicted in Table 4. These methods may be some type of surveying either by conventional surveys in the pit floor or by photogrammetrics. Use of these methods will determine bank overburden quantities necessary to uncover the coal; by determining actual dragline cycle times, exact rehandle percentages can be derived.

In addition to the prominent position of draglines in overburden removal from coal, they have been similarly applied to other minerals. Some of these include iron, phosphate, bauxite, alluvial gold, aggregate rock, and laterite.

Extended Bench Operation: The extended benching technique allows the dragline to handle overburden covers that are beyond its normally rated range. Thus, in situations where isolated pockets or consistently deep overburden covers are encountered, the dragline, by extending its bench, is able to mine areas beyond its normal reach capability.

This technique is based on extending the dragline support level out from the old highwall and closer to the spoil. This is accomplished by casting material over the edge of the old highwall and building the extended bench. The extended bench material may be moved either by the dragline and/or by dozers and normally would come from one or a combination of two places depending on the situation. In a simple side casting situation, the material would come from the key

Fig. 6. Detailed geometry of revised rehandled portion.

Table 4. Formulas for Calculation of Revised Rehandle Wedge

Mathematically, the end area of the rehandled portion can be calculated by the formula:

$$A_1 = D^2 \div \tan \phi \quad (1)$$

where A_1 is the end area of the normally assumed portion of rehandle bounded on one side by the previously cut highwall, D is the depth of cut, and ϕ is the highwall angle (see Fig. 6 for diagram).

The additional end area of the rehandle portion is derived as follows:

$$y = D \div \sin \phi \quad (2)$$

where y is based on triangle $p \epsilon \beta$

$$\angle p = \phi - 1.3 \alpha \quad (3)$$

where p is an angle within area A_2 , and α is the natural angle of repose of the loose spoil.

$$\angle \beta = \alpha + 1.3 \alpha \quad (4)$$

where β is a second angle within area A_2 .

$$\angle \epsilon = 180^\circ - p + \beta \quad (5)$$

where ϵ is the third angle within area A_2 .

The end area of the additional rehandle portion can then be calculated by the formula:

$$A_2 = \frac{y^2 (\sin \epsilon) (\sin p)}{2 \sin \beta} \quad (6)$$

(see Fig. 6 for diagrammatic representation).

Total end area (A_T) of this is now simply computed by the formula:

$$A_T = A_1 + A_2 \quad (7)$$

Fig. 7. In simple sidecasting situation, material comes from the key cut.

cut. In an advanced bench situation, the material would come from the key cut and the advanced bench chop-down area. Figs. 7 and 8 show plan and cross-sectional views for both situations. The material from the advanced bench area can be used only if it is stable and can support the dragline. Once the material is leveled and a base is prepared for the dragline, the machine can reposition itself on this extended bench and remove material from the final cut and the previous extended bench. See Figs. 9 and 10.

By using this technique the dragline is able to dig overburden covers that create soil piles beyond the reach of the machine. However, rehandle situations are created with rehandle volume dependent upon overburden depth. Careful study and close supervision are essential with extended bench operation.

Power Shovels

Two types of mining shovels currently in use are stripping and quarry. The two machines differ mainly in the duty they perform. A stripping shovel is associated almost exclusively with coal mining for overburden removal. The stripping shovel places the overburden beside itself in the mined out area. Mechanically the two shovel types are similar, but the

stripper is overall a much larger machine with greater overall digging range.

A quarry shovel is used principally for open pit mining loading into trucks or rail cars. The quarry shovel is the workhorse of difficult mining and rock waste removal. In recent years the hydraulic shovel has challenged the traditional power shovel in some of the harder digging materials, but it will not supplant it in the overall excavation of hard rock in large open pits. Where overburden and ore are hard rock, requiring drilling and blasting, a shovel section will provide maximum loading flexibility. Where a transport unit must be loaded by the excavator, the shovel "spots" a target more accurately and less spillage results.

Shovels require good underfoot conditions, which dictate a hard rock overburden condition. In the larger sizes, lower groundbearing pressures for the excavator favor the dragline. In planning any overburden stripping program, consideration of the soil and/or rock physical characteristics must be made. Acceptable slope stability conditions may require extensive enlargement of an open pit to ensure good bench safety. Highwall conditions in coal mining may dictate the amount of overburden unloading required for pit safety.

Capital cost of power shovels is expensive compared to

Fig. 8. In advanced bench situation, material comes from the key cut and advanced bench chop-down area.

Fig. 9. Dragline repositioned on extended bench.

dozers or rubber-tired loaders. Where shallow hard rock overburden and waste occur, plus a small or moderate production rate, loader selection may not necessarily favor the shovel. Power shovels have relatively long depreciation periods requiring an appropriate mine life to obtain favorable ownership costs.

Although the stripping shovel works principally in coal overburden removal, it is applied in the mining of phosphate, bauxite, ironstone, gypsum and others. The stripping shovel, as the name implies, works the overburden in long narrow strips, dumping the waste in the adjoining mined out area. Following the stripping operation, the underlying ore can be removed, usually by a different machine. Under normal stripping conditions, the shovel is capable of average faster cycle times than the dragline (Rumfelt, 1968).

For a stripping shovel pit, geometry limits its digging depth by the ability to pile the waste away from the ore. Waste spoil piling then becomes the design limitation for a particular shovel size. A "usefulness" concept related to gross shovel weight has been developed: usefulness is defined as the dumping reach multiplied by the nominal size of the dipper (Rumfelt, 1968). This concept can help in early eval-

uations of stripping projects and in the estimates of shovel size requirements.

The increased mining of both single and multiple seam coal in the western United States has developed new and innovative techniques for overburden removal. In rugged terrain overburden is being stripped with quarry-type shovels loading trucks. One western operation using draglines for stripping is assisted by shovels and trucks.

These remove the first bench of the overburden and the dragline then moves in to open the box cut making room for the spoil (Jackson, 1979). When the bench has been widened to six cuts by the shovel, the drill crews can operate safely ahead of the pursuing dragline. Pit length ranges from 1.6 to 6.4 km (1 to 4 miles).

BWEs

Originally, these excavators were developed for relatively easy digging materials. These included gravel, sand, loam, marl, clays, and lignites. Today one of the outstanding successes for BWEs is in overburden removal in the easy digging lignite brown coalfields of the Federal Republic of Germany. However, the newer generations of BWEs have incorporated

Fig. 10. Repositioned dragline removing material from the previous extended bench.

modification designs giving them better operating characteristics for more difficult digging materials. Their use is now extended to highly compact sediments, shales, black coal, some limestones, tar sands, and others. Although blasting of some of these materials can assist wheel digging, normally rock-type materials needing blasting should not be considered for BWEs.

Bucket wheel/belt conveyor transport systems can achieve high production rates. Recently a new class of giant excavator went to work in Germany handling up to 240 000 m³ (8,475,474 cu ft) per day. This is equivalent to handling 5.3 m³/s (187 cfs).

This BWE has frequently exceeded the rated capacity with rates to 254 000 m³ (8,969,877 cu ft) per day in good digging (Anon., 1976). At the same time, the BWE can offer the operator in shallow ore horizons the advantage of precise cutting of overburden, using small buckets, and near 100% ore recovery.

The BWE is used to load trucks but few examples exist, since the belt conveyor is the preferred method. BWEs are continuous excavators that produce a constant flow of material. To maintain truck loading requires a continual queue-up to keep a unit always under the loading conveyor of the BWE.

Because the BWE has less operating flexibility than shovel trucks, a careful study must be executed before selecting the machine. This includes detailed pit layouts based on explo-

ration results and geology of the deposit. The object of this is to keep the relocation of excavators and conveyor belts to a minimum. To avoid relocations, the size of the BWE in terms of output and maximum vertical digging reach must be chosen in line with the maximum depth and output of the pit (Beneche, 1982). As a rule of thumb, the vertical reach of the BWE, when added for all mine units, should equal the pit maximum depth.

Since large BWEs are only suitable to long-term operations because of their high capital cost, they can compare favorably with draglines and power shovels in the following: (1) instantaneous power demand, (2) weight to output ratio, (3) loading shocks, and (4) power consumption (Aiken, 1968). BWEs have the additional advantages of having (1) wider operating benches and more stable pit slopes, (2) improving a shovel efficiency in underlying hard rock when soft overburden is removed with a BWE, (3) close control in selective mining, (4) easier and cheaper rehabilitation of overburden spoil, (5) the exposure of more reserves with wider benches, (6) an ability to deliver material both above and below the working level, and (7) the ability to make high and/or deep cuts (Aiken, 1973).

Selection of a BWE for a specific production rate can be more complex than for other excavators. Shovel output and digging factors are well established for power shovels. This is not true for the BWE, since within a basic size range, machines of equal capacity can vary in profile dimensions,

weight, horsepower, etc. (Aiken, 1973). The often-quoted theoretical BWE output should be derated for practical planning purposes. One manufacturer gives the following derating factors for 3, 2, and 1 shift operations:

3 shift, 0.6 (5000 hr)
2 shift, 0.7 (4100 hr)
1 shift, 0.8 (2300 hr).

A complete system may include a belt wagon, hopper car, cable reel car, mobile stacker, and other special conditions of operations. When these elements are all considered, the overall BWE availability may fall below 50% of the total calendar time. This is usually a good starting point when making a preliminary selection of a BWE size if the system is complex.

Digging height and cut width will be proportional to the boom length. Design features that add greatly to machine cost are increases in the digging ladder, subgrade digging ability, and increases in the normal wheel and bucket size. When these weights can be reduced, a 5 to 10 times weight reduction for the total machine can be expected (Aiken and Wohlbiel, 1968). BWE efficiency will increase with greater digging and cut heights, but this must be evaluated on the

basis of the operating plan and the total economics. Good mine layouts in planning are major factors in reducing operating as well as capital costs.

In a selective removal of overburden from a pay horizon, it may be found more advantageous to use two smaller machines rather than a single BWE. Production efficiency may be greater in small diameter wheels than in large ones. This is true because it uses a greater effective wheel diameter in digging an equal slice thickness than the larger machine. Two-thirds of a wheel diameter is approximately the optimum one pass digging height, favoring the larger BWEs for thick overburden and smaller wheels for thin overburden and selective separations (Aiken, 1968).

Fig. 11 shows three typical methods of BWE use for overburden removal (Gold and Gold, 1974). These visualize the possibilities for selective mining of overburden or stripping waste from a pay horizon.

Other considerations in the selection of a BWE are the type of bucket, the tooth design, transfer feeder for material from the wheel to belt, wheel drives, suspension systems, and boom type. Information on these elements has been discussed in detail in the first edition of *Surface Mining* and also in the *SME Mining Engineering Handbook*, Section 17.3.2 (Aiken, 1973).

Fig. 11. Three typical methods of BWE use for overburden removal.

Dredging / Monitors

These two wet methods for excavating overburden may be treated together. Both may involve pump selections, pressure heads, and production of a slurry. Monitors are sometimes mounted on the bow of dredges to cut down dangerously high digging faces. Hydraulic monitors are more frequently used in land-based stripping operations. Soft, easily eroded materials are typically handled by monitors, whereas dredges are equipped to handle a wider range of material hardness.

Dredges are either classed as bucket line or hydraulic. The removal of water-saturated materials may also be done with a barge-mounted clamshell or drag bucket. These have minor use for application to overburden removal and are not considered here. Both hydraulic and bucket-line dredges have been used for overburden removal.

Because most water-saturated overburden is not very difficult digging, it would be unusual to find an economically justified case for dredging by a bucket-line dredge. These may be as much as 1.4, or even more, in capital cost over a large hydraulic dredge of equal capacity and digging depth. Almost the only circumstance justifying overburden removal by bucket-line dredge is a situation in which the underlying pay mineral is dug by the same machine. This presents obvious problems in providing a continuous flow of mineralized material. To avoid this problem, a two-ladder bucket-line dredge was once considered for a tin property in Malaysia (McKay and Davis). For all practical purposes, the hydraulic cutterhead dredge for overburden is the only machine to be considered.

A recent innovation in dredge design has been the combining of a bucket wheel fitted ladder and a bucket-line ladder dredge into a single machine, the idea being that the BWE will dig overburden ahead of the bucket-line ladder digging the underlying mineral-bearing horizon.

The most simple hydraulic dredge is a pump, barge-mounted, connected to a hinged suction pipe that can be submerged at an angle of 45° below the horizontal. Material recovered is pumped via a floating pipeline to a discharge area. In harder materials, the suction pipe may carry an independently driven toothed cutterhead. With an increase in dredge size, power, and digging depth, more sophisticated controls and equipment add greatly to the capital cost.

Large cutterhead hydraulic dredges are capable of digging difficult material. In-place coral and blasted rock have been handled successfully. The hydraulic dredge is at its optimum efficiency when used to excavate and transport overburden from lode or alluvial deposits at sites distant from the mine area (Barker and McKay, 1972). A dredge can provide continuous excavation with comparable availability, or better, to other machines including the BWE (Barker and McKay, 1972).

Both bucket-line and hydraulic dredges always operate in prepared ponds that allow for water control. This includes water quantity, turbidity, and pond level. The dredge can operate at either higher or lower elevations by control of the pond level. Above water dredging faces are normally limited to about 1.6 m (5 ft) for hydraulic dredges and 4.6 m (15 ft) for bucket lines. Dredge faces that slough to the pond may be carried higher if caution is exercised. Under these conditions one Australian sands operation carried a face approaching 70 m (230 ft). To safeguard the dredge, bow monitors knock down the high sand face to a safer angle.

Designing and building hydraulic cutterhead dredges to handle up to 3800 m³/hr (134,195 cfm) or bucket lines to dig up to 2000 m³/hr (70,629 cu ft per hr) in harder ma-

terials is not a problem. Jet lift or jet assist as a device for increasing the upward flow of solids toward the suction pipe has been used successfully in loose material.

This has been pioneered by the Elliott Machine Corp. and their machine is called the *Dragon Wheel*. The Dragon Wheel can operate with equal efficiency in either direction of swing. This has resulted in a 2:1 improvement over the conventional cutterhead and even up to 3:1 increase in output. The underwater BWE dredge is reported to have eliminated former objections by placer miners to hydraulic dredges. See Fig. 12.

Dragon Wheels are presently (December 1982) operating at 23 sites throughout the world. Where these machines are applicable, Dragon Wheels will have a lower first cost than a comparable bucket-line dredge. Units built to date have been in the range of 75 to 1119 kW (100 to 1500 hp) (McDowell, 1980).

In easy digging overburden, a 406 mm (16 in.) discharge rated dredge would handle about 45 400 L/min of slurry at 15 to 20% solids (12,000 gpm). This would be pumped at 6.1 m/s (20 fps). Pumping power would be about 825 kW (1100 hp). Where pumping head conditions may vary, a nominal kilowatt dredge pump rating is selected and a booster pump may be used for head increases.

Hydraulicking monitors, in addition to their use with dredges for reducing hazardous bank heights, have been successfully used as the prime excavator for overburden removal. Material, ideally, should be of a sandy nature with only a minimum of clay and not compacted. A sandy slurry produced at densities up to 50% of volume may be achieved, but during operations will vary constantly. Where the clay content is high, free hydraulicking is less successful. In the sandy-clay material of Florida phosphates, monitors are always assisted by draglines. These do the excavation and the monitors pulp the loosened clay materials. At one bauxite operation, when clay was encountered, the hydraulicking efficiency was reported to fall off rapidly.

Test work has indicated that sandy slurries will flow on negative 2% gradients. However, contained rock and boulders are not moved easily from the face until downhill slopes exceed 5%. Optimum mixing of solids and water is best achieved on very steep gradients of +20%. In all instances of free face monitoring, the operation efficiency is enormously increased by slot dozing material to a slurry mixing point. This method is helpful in reducing overall pusher distances. Trials should be conducted to determine the best range of distances for monitors from the sluicing face.

A case history is described in a later part of this section where 32 Mt (35 million st) of overburden was removed from one of the world's largest copper ore bodies. Another unique monitor application for overburden removal was applied by Alcoa in Suriname. This is described later more fully, including updated cost estimates (Koch, 1975).

OVERBURDEN TRANSPORT

Excavator Transport

The choice of the transport method for the excavated overburden must be in harmony with the type of excavator. There are some combinations that will not be acceptable and others will have a broader range of acceptability. It is relatively easy to reject the noncompatible methods, but those fitting multiple combinations must be considered carefully to reach an optimum solution. This may also include a combining of more than a single method of transport. All feasibly

Fig. 12. Dragon Wheel BWE hydraulic dredge.

applied transport methods are discussed as to compatibility with the excavator options.

Trucks

These can be considered the workhorse of overburden transport machines. Trucks offer maximum flexibility of operation in equipment size, trafficability, engine power, material adaptability, and the matching of the excavator. Trucks perform well in all types of climates and operating conditions. This has made them very attractive as transport around the globe.

Truck units come in a variety of configurations to fit almost any type of overburden removal operation. The choice of a truck depends on the conditions of each case. Overburden is mainly moved by the standard, two-axle end dump truck. The body of this truck can be loaded by shovels, front-end loaders, draglines, BWEs, and even dozers working with belt loaders. In special conditions, the three-axle truck may be employed. End dump design is the best method when dumping over the edge of an advancing fill. Most overburden is not free flowing, but rather a loose material mixed with nonuniform rock or blasted rock of varying sizes. This requires the open design of end dump units, but a few special cases may permit the use of the bottom dump truck. The unit can be very useful for moving a soil overburden free of large rocks, since it can spread and compact the material in one operation.

Trucks should be size related to the intended excavator. On average haul distances, the excavator should be able to fill the truck body in three to five passes. Filling of the truck body must be in agreement with the truck weight-carrying ability. Overloaded trucks will be subject to excessive tire wear and abnormal operating costs. Therefore, bank and loose material unit weights must be considered when body sizes are selected for a specific truck.

In operations where overburden removal will continue for the economic truck life period, the body size choice may be based on hauling a single material. Where truck interchangeability is planned with the ore hauling operation, body size should be carefully considered. Very often the ore may weigh considerably more than the overburden, creating a potential for overloading trucks designed to carry the latter material. Either the owner must rely on underloading of ore to overburden trucks or select a single truck capacity for carrying both materials. Fuel and labor costs have forced owners to periodically review the advisability of switching from trucks to other systems, such as conveyors, in-pit crushing with conveyors, or electrification of long, fixed uphill hauls with trolley-assisted trucks.

Belt Conveyors

Large increases in fuel costs over the last 15 years, and the fact that truck haulage may amount to 50% of the mine direct costs, have created strong interest in belt conveyor

transport. Large-scale conveying is not new. Several metal mines, including the alluvium overburden removal phase at Twin Buttes, Arizona, have successfully used conveyors. Overburden at Twin Buttes was handled by scrapers without crushing in the pit. Dumping was to a grizzly hopper feeding a belt system. At another operation, a glacial moraine overburden was stripped from an iron ore deposit and conveyor transported about 4.8 km (3 miles). A dragline excavated the material and discharged to a portable hopper. Oversize was scalped at the hopper before feeding the belt conveyor.

A common application of conveyors is in a shiftable system where the excavator is a BWE. In most cases of a single bench, the system operates on the same level as the excavator. This feeds to a face conveyor that discharges to an extensible conveyor removing the overburden from the pit. The extensible conveyor allows the face conveyor to be shifted forward with minimum lost time. Overburden is either moved out of the mine area or deposited in the mined out areas of the pit.

The belt-conveyor, compared with truck haulage, is more energy efficient, less labor-intensive, and more inflation-proof. To expand the use of belt conveyor systems to more difficult materials has required the introduction of mobile crushers. Although they may be fed with either a power shovel or dragline, the latter may be more cost effective as a volume producer. The choice may be dependent on the mine plan and work the excavator must do. Combining the dragline with a belt conveyor system and mobile crusher utilizes proven cost-effective tools, increases productivity, and allows

for greater overburden depth mining (Frizzell and Martin, 1977).

A combined dragline-crusher-conveyor system requires a surge hopper to ensure uniform belt loadings. The extra surge capacity covers intermittent digging cycles and minor operating delays. Past experience suggests that a top opening on the hopper of 13×13 m (43×43 ft) may be minimum for a dragline of 30 to 53 m³ (1059 to 1871 cu ft) bucket volume. The operator must hit this dump opening with a minimum of delays and spillage.

The US Bureau of Mines (USBM) sponsored a program concerning the development of in-pit crushing and belt conveying methods. Incentives for such a program stemmed from the rising costs of truck fuel and the high cost of developing alternative fuel sources. A multimine survey was conducted that clearly indicated a need for in-pit crushing and conveying (Johnson, Frizzell, and Utley, 1981). Their study showed large movable gyratory crushers to be the only practical crushing solution and such a system has been designed. Several commercial installations exist at this time and the concepts appear practical and economically effective. In those areas of the world where fuel costs have been substantially higher than in the United States, direct feed to overburden handling conveyors has reached an advanced stage of technical development and application. Table 5 is a summary of mine operating conditions as determined in the USBM-sponsored study.

USBM examined several designs for movable in-pit crushers. They all included the same elements of design shown in

Table 5. Summary of Mine Survey Data

	Composite Data from Iron Mines Surveyed	Composite Data from Copper Mines Surveyed
Pit Characteristics		
Maximum haul grade, %	10%	10%
Average bench width	215 m (700 ft)	75 m (250 ft)
Bench height	12-14 m (40-45 ft)	12-14 m (40-45 ft)
Expected change in depth (per 5 years)	60 m (200 ft)	45-150 m (150-500 ft)
Truck Haulage		
Number of ore trucks	47	20-60
Number of waste trucks	47	20-60
Capacity:		
Unit ore capacity	90-154 t (100-170 st)	90-180 t (100-200 st)
Unit waste capacity	90-154 t (100-170 st)	90-180 t (100-200 st)
Average number of shovels	14	9
Shovels, size	11 m ³ (14 cu yd)	7.5-15.3 m ³ (10-20 cu yd)
Rock/day:		
Ore	58.3 kt/d (60,000 stpd)	36.3-110 kt/d (40,000-120,000 stpd)
Waste	40.8 kt/d (45,000 stpd)	72.6-81.5 kt/d (80,000-200,000 stpd)
Hauls		
Ore, length	4.8 km (3 miles)	2.4 km (1.5 miles)
Waste, length	3.2 km (2 miles)	3.2 km (2 miles)
Ore, climb	73 m (240 ft)	84 m (280 ft)
Waste, climb	76 m (250 ft)	150 m (500 ft)
Ore, time (min/load)	17	25
Waste, time (min/load)	23	25
Maintenance		
Average haulage (men/unit)	7	5
Average fuel consumption	1550 L/d (410 gal/d)	1890 L/d (500 gal/d)
Crusher		
Number	2-4	1-2
Size	1525 mm (60 in.)	1525 mm (60 in.)
Capacity	3630 t/h (4000 stpd)	2270-3630 t/h (3000-4000 stph)

Fig. 13. Movable crushers with crawler transporters.

Fig. 13 but with individual adaptations to a unique pit problem. USBM survey results indicated more variations in conveying systems than in the crusher. Fig. 14 shows a very workable system that could be adapted to thick overburden. A crusher of this type may result in a lesser cost than a fixed crusher housed in a conventional concrete structure (Johnson, Frizzell, and Utley, 1981).

The first major, high capacity, in-pit ore crushing system was installed at Duval's Sierrita copper-molybdenum open pit mine in Arizona. Crusher capacity is up to 3.6 kt/hr (4000 stph) using a 60×89 gyratory. Duval estimates the system will save \$8 to \$10 million a year in operating costs (Anon., 1982). Pit trucks dump to a portable apron feeder linked to the crusher. The entire system is moved by a crawler-type transporter. Duval will license the system to others under a technology agreement (Anon., 1982).

Railroad

When a high production rate can be maintained over a long period of time, the railroad will provide the lowest cost per ton of any system (Shand, 1970). The railroad has a high initial cost that severely limits its use for overburden. When rail haulage is used for overburden, the track system has been designed principally for ore movement. In most cases, the overburden if transported by rail is done because the system is installed to handle ore.

Most waste is disposed of by dumping from a higher elevation with an outward building pile being formed. This can only be done by railroad if side dump cars are used. Due to the side dumping mechanism, the cars are heavier and

more costly than flat bottom ore cars used in a rotary dumper. Train length is usually limited by the extra weight of side dump cars. Waste dumps created by side dump cars must have the track shifted outward as the dump grows and may be more costly to maintain than those made by trucks. On the other hand, a very long dump section of track on the edge of a deep canyon may be very practical. This may create visibility problems for the train engineer, but it may not be important if a two-way radio is used to keep the locomotive engineer informed of the train movement and dumping progress (Aiken, 1970).

Rail movement of waste is probably only justified where the main mine ore transport is by rail and waste and ore car interchangeability is practical. Waste volume should also be large to experience the low costs of rail movement. Some of the advantages of rail waste hauls are: (1) relatively small labor force for potential tonnage moved; (2) can handle wide range of materials and big volumes; (3) low cost for long hauls; and (4) can be remote-controlled. The major disadvantages of a rail system are: (1) high initial cost; (2) grade design limitations; and (3) inflexibility of the system.

Hydrauliclicking

This can be termed the excavation of unconsolidated or loosely consolidated materials by the impact of high pressure water, or in areas where frozen material is being removed after thawing. Both mining and transportation are by the same medium. Special nozzles, giants or monitors, are used to break down the materials with pressures of 5273 g/cm² (75 psi) and higher.

Fig. 14. Movable crusher concept with constant feed.

Modern-day hydraulicking tools are more efficient than the old equipment of years past. The equipment is more mobile and controls are easier to operate and may be automated. Pipe size to weight is better, making site moves faster. Monitors can be remotely operated for better water control. No longer are clumsy jockeyboxes, heavy skids, and deadmen needed as well as the hard-to-control straight pipe monitors. The present-day monitor uses hydraulic thrust for easy precision positioning control.

Old time hydraulicking was mainly concerned with moving alluvial gravels through a sluice to recover minerals. Today's monitor can handle twice as much yardage when used for stripping or washing material. This can be verified by inspecting old monitor production tables.

Conditions that must be met for successful hydraulicking are: (1) sufficient water; (2) spoil disposal area; (3) sufficient runoff gradient; and (4) amenable material.

These parameters apply for unassisted *free* hydraulicking. For materials of a more compact nature, hydraulicking techniques today employ a bulldozer. It can rip and doze semi-compact material to a slot trench. Monitors are directed into the trench to further disintegrate and transport the material.

Dredging/Pipeline

The hydraulic dredge previously has been described as an excavating machine. Its pumping aspect is often incorporated as a transport tool as well, aside from discharging excavated material back to the pond. One of the best examples of a dredge and slurry pipeline transport is the overburden stripping at the Caland mine. The ore body was under 30 m (100 ft) of water and overlain with an average of 90 m (300 ft) of overburden. This 124 million m³ (3.5 million cu ft) of overburden was transported 6 km (4 miles) to a disposal site (Li, 1976).

Two 7900-kW (10,600-hp) dredges did the pumping of the slurried overburden. Material was handled at the rate of 2700 m³/min (3500 cu yd per min). The entire job was completed in about seven months from start of pumping. A more recent (1976) slurry pipeline project at Caland was the removal of some 203 000 m³ (265,000 cu yd) of erosional silt. This material resulted from erosional deposition of silt into the mine area.

The 1976 project was carried out by slurrying the silt with a Marconaflo system, a patented device that uses a gooseneck swivel nozzle to produce a high pressure water

jet. Impact of the water slurries the material and a caisson unit with a top suction vertical centrifugal pump receives the gravity fed slurry. The pump and nozzle are located at the bottom of the caisson unit. See Fig. 15. Sinking jets are provided below the units to allow the caisson to settle into the material. To operate fully submerged, the pump drive mechanism is interfaced at the top of the unit with the drive motor at the surface. Macronaflo units have been considered for other overburden removal projects where a siltlike material may exist (Schabas, 1976).

Of interest is another device used for overburden removal of a low bearing-pressure material. Because of this, a special crawler-mounted slurrier was developed. The machine has an open-faced jaw crusher mounted on the front of a hydraulic gun car, typical of those in use in Florida phosphates. The difference is the addition of the hydraulically operated movable jaw grizzly that is designed for vertical movement above and below the level of the crawler tracks. Plus 15.2 cm (+6 in.) rocks washed into the crusher sump are reduced by the 182 000 kg (400,000 lb) pressure exerted. The slurry at 25% solids is pumped to a constant level sump, monitored by sensing devices, and through a 50.8-cm (20-in.) pipeline to a discharge area 10 km (6 miles) away. Instrumentation and monitor panels ensure that any malfunctions are immediately detected (Koch, 1975).

Some of the advantages claimed for this system are: (1) increased safety, can operate at distance from vertical face; (2) low cost transport; (3) higher tonnage per dollar of capital; (4) low labor costs; (5) can get equipment without delivery delay; and (6) can operate in any weather.

Transport Combinations

This section has discussed specific transport schemes as single methods, but for major economies in moving overburden, some of the methods may be combined. These combined methods may have interest stimulated by the increased cost of all forms of energy.

Fig. 15. Marconaflo system for slurrying the silt at Caland mine.

Probably the combination of widest interest to the surface miner is the truck and conveyor system. In this system, the truck hauls are minimized by establishing a conveyor loading station at or within the mine itself. Depending on the nature of the overburden, trucks may dump directly to a hopper feeding the conveyor belt or to a mobile or semimobile crusher ahead of the conveyor system. When truck hauls can be maintained on level profiles and short runs, the cost effectiveness of this combination is maximized. Systems of this type are currently (1987) being installed in copper mines in the United States and Chile.

CASE STUDIES

Iron

In order to meet planned annual production rates, ore grades, and blending requirements, iron ore operators must design carefully for overburden stripping programs. Unless the stripping can expose enough crude ore to meet the mine commitments, shipments will fall behind and/or material grade will suffer.

This case study examines a mine where the overburden stripping program had to be designed to meet established factors. Among those considered was planning to smooth out the overburden removal rate.

An equipment fleet should be ideally planned so excess capital spending is not required initially. This may require a gradual planned increase of the fleet to be phased with ore production. As the rate of overburden removal decreases, equipment can be transferred to ore mining operations. High stripping rates in early years may be justified if the stripping time span is similar to the equipment depreciation schedule.

This case deals with the problems of removing and disposing of two types of overburden material: alluvial and rock waste.

Project Criteria: *Topography:* Alluvial valley with ore in prominent hills of low relief. *Climate:* Warm to hot summers with heavy rain at times. *Elevation:* 40 m (131 ft). *Operations:* 330 days per year, three shifts per day, 8 hr per shift, and 75% operating efficiency. *Material:* Alluvium, 1.7 t/m³ (0.53 st per cu ft); rock, 2.7 t/m³ (0.084 st per cu ft).

Selection Parameters: The primary requirement to be met in the overburden stripping was the removal of sufficient barren material to allow for a blended plant feed. This was a constraint imposed by the project costs and metallurgical requirements. Two types of ore had to be blended in equal proportions until the capping ore was exhausted.

To satisfy the 50/50 blend to the mill, 48 Mt (53 million st) of alluvium had to be removed in 24 months. About 89 Mt (98 million st) of rock waste had to be moved concurrently. The quantities of overburden were calculated by a computer program based on exploration input. This is shown in Table 6, a sample printout giving the ore and waste/alluvium amounts in the initial pit. The term overburden here refers only to the alluvium with waste representing the rock overburden.

Level-by-level printouts were made for the start-up mine pit. The results of this were graphically plotted, as seen in Fig. 16. This indicates the need to remove nearly 120 Mt (132 million st) of overburden, to 120 m (394 ft) deep, to expose the required 50/50 mixture of two ores.

Alluvium Alternates: Soil borings and test pits indicated the soft, unconsolidated nature of the alluvium. It ranged between clays, sandy clay, and loess. Fig. 17 shows the relationship of the overburden to the ore zone. The rock waste must be classed as overburden since it had to be removed

to reach the ore. The time frame of the overburden removal scheme was paramount to the method selected.

Two alternate schemes were applied and estimated for capital and operating costs. Based on the experience of a large open pit in the southwest United States, it appeared rubber-tired motorized scrapers would work well. These machines are particularly suited to soft, sometimes moist, loose overburden. Combined with the scrapers was a belt conveyor loading station and overland belt.

The second alternate considered was an all scraper fleet delivering the alluvium to the dump site. This is the same location in both alternates. Although other feasible methods were technically acceptable, the ones discussed here were selected as best fitting a restricted time frame imposed on the operations start-up.

Comparison Methods: An all scraper fleet was compared with a scraper fleet delivering to a drive-over hopper feeding a belt conveyor system. Delivery of material from both systems was to the same disposal site. This site was adjacent to the open pit that would be eventually refilled with the overburden. Refilling was a requirement to free up agricultural land that was temporarily holding the waste dumps.

The optimum scraper size was determined by computer haulage simulation. This indicated the largest size scraper available to handle over 22 kt (24,250 st) per shift. A belt conveyor 1.22 m (4 ft) wide by 3.4 km (2 miles) long was used in the combined scheme. At the discharge end of this method, bottom dump trucks were used to distribute the alluvial overburden to the waste area. Fig. 18 illustrates the system components. Table 7 is a typical haulage simulation computer output.

A second computer program, using scrapers, assigned operating costs for the trucks and conveyor system and calculated the optimum number of units to work with the conveyor. From these data, the system capital and operating costs for a unit of material were estimated.

Similar procedures were followed for the alternate alluvial overburden method. This was the application of an all scraper fleet to load and transport the material. The ability of scrapers to dig, load, and transport and discharge, with travel speeds to 50 km/h (31 mph), made this study of interest. After analyzing the total costs of the system, the comparative study results favored the scraper/truck scheme with a conveyor belt by 13%.

Fig. 17. Typical mining cycle for overburden removal.

Fig. 18. Scraper/belt system.

Rock Overburden: To begin mining and have an advance supply of ore available required removal of waste rock at 35.7 Mt/a (39,352,500 stpy). In the overburden removal program, this rate would continue for 30 months. The rock material, with an average compressive strength of 1360 kg/cm² required drilling and blasting.

The criterion of having to expose two types of ore for the initial mining required taking the removal rock overburden to the -120 m (-394 ft) pit level. Graphically this is demonstrated in Fig. 17, showing the complete cycle of overburden removal for alluvium and rock. The program would cover a total development time of 30 months. Total material removed, alluvium and rock, would amount to 137.25 Mt (151.29 million st).

Two alternates were studied for overburden rock removal. Alternate one was front-end loaders working with 109 and 154 t (120 and 170 st) trucks. Alternate two examined many combinations of truck sizes, 109 to 317 t (120 and 350 st) and electric power shovels, 11.5 to 38.2 m³ (406 to 1349 cu ft). See Table 8. Performance output of the equipment was determined by computer simulation. The same programs were used as those applied to the alluvium.

The comparative results indicated that the front-end loader and truck combination was the most economical. This was particularly true when trucks were loaded from each side in the model. Recommendations for the rock overburden removal equipment combined the front-end loader and truck fleet with power shovels. The decision to include power shovels was based on the need for loading from high benches, interchangeability of loaders for ore work, and an owner preference for power shovels over front-end loaders.

Phosphate

In this case, the overburden consisted of well-consolidated but relatively soft siltstone or fine-grained sandstone. The formation was thinly bedded and contained some very hard chert beds. This meant that some blasting would be required prior to removing the harder material.

Topography of the area was flat to gently rolling. Dissecting river and creeks, generally dry, cross the mining area. The generally flat terrain lent itself to dragline operation with no need for extensive cutting to maintain operating grades for the dragline tub. Locally, the formation is gently

folded tending to let the overburden depth vary tens of feet over a horizontal distance of several hundred feet. This uneven occurrence of the overburden interface with the matrix contributed to the choice of the dragline. Fig. 19 shows this uneven overburden-ore interface.

Alternative overburden removal schemes to the dragline were studied. All draglines for both overburden and ore were considered. The ore matrix would be delivered to conveyor loading points for transport to the washer.

Motor scrapers were estimated as too expensive due to their high consumption of diesel fuel. In this case, available natural gas for power generation offered very low unit kilowatt per hour costs. On the other hand, trucking costs were \$0.085 per ton mile in the year of the study vs. electric power at \$0.0083 per ton mile.

In exploration the chert had been shown to break into boulders up to 610 mm (24 in.). The slopes of the four-year-old exploration trenches maintained verticality, but the material in the ravelled state reposed at 26° to 30°. This required the draglines to deposit overburden well off the matrix to be mined.

All the overburden was densely packed and would offer firm resistance to a dragline bucket. This was especially so since the drag direction was parallel with the hard surfaces of the cherty horizon. Experience in working the relatively light material, 1.71/t/m³ (0.05 st per cu ft), indicated sufficient competency to justify light blasting before loading. A powder factor of 0.17 g/t (0.0003 lb per st) was sufficient to loosen overburden without mixing with the phosphate matrix.

Project Criteria: Overburden production: 22 400 000 m³/a (29,298,102 cu yd per year). Operations: 340 days per year, 21 hr per day. Average hourly production: 3100 m³/h (4055 cu yd per hr). Slopes: Final face, 55°; working face, 45°. Swell factor: 0.80.

This particular deposit was complicated by having multiple matrix horizons. Overburden stripping requires careful planning to avoid raveling of the dumped overburden over the lower cut matrix. Also, development of the multiple matrix lenses had to be done so that ore mining and overburden stripping could be done together. This required stripping the upper matrix level and immediately following with the mining to permit the dragline access to strip the lower horizon. Fig. 20 illustrates the proposed mining sequence with the offset bench method. Ore matrix was taken by shovel and truck operations.

Table 9 shows the calculation of the dragline output. Self-loading scrapers were selected for bench preparation ahead of tub moves, to do some stripping in very deep overburden areas, and for land rehabilitation work. In addition, the other major auxiliary equipment provided were bulldozers and a motor grader.

Laterites

These materials are the end product of long tropical weathering of serpentinized ultramafic rocks and the derived clastics. Laterites are developed in situ. Where they are nickeliferous, there are often well defined physical and mineral grade differences on a sharply defined horizontal basis. It is not uncommon to have to remove an upper horizon of lean

Fig. 19. Geologic cross section of the phosphate operation showing uneven overburden-ore interface.

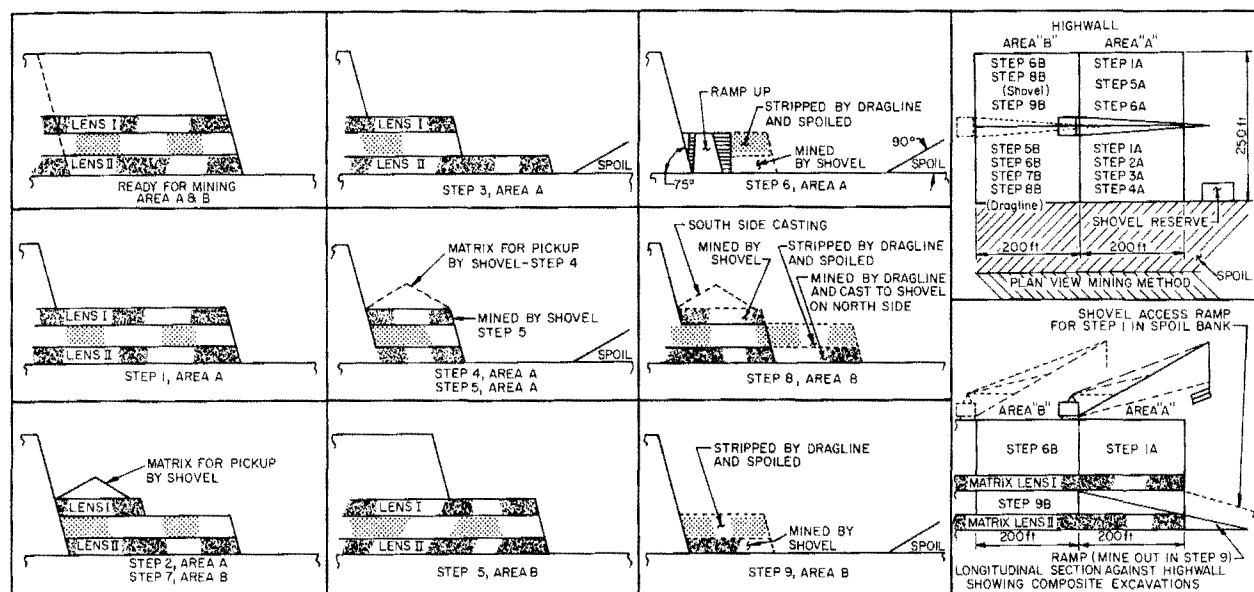

Fig. 20. Proposed mining sequence with the offset bench method.

Step 1. The dragline excavates the full width of the cut to lens I, developing sufficient matrix to occupy the shovel in the same area until reaching the location of two lenses. At this point, the shovel schedule should be such that a reserve area of matrix is left behind while the shovel starts mining matrix in the immediate area of the dragline.

Step 2. The dragline mines matrix in the southern half of the area, casting back to the northern half for loadout by the shovel.

Step 3. The dragline strips waste in area A to lens II.

Step 4. The dragline mines matrix from lens II, area A, and casts back to the north for loadout by the shovel.

Step 5. The dragline strips overburden above lens I, area B, on the south side. The shovel mines out lens I, area A, north side, and retreats to the reserve loading area to continue mining matrix.

Step 6. Waste is excavated by the dragline above lens II on the north side of area A, leaving a ramp into area B. The dragline continues stripping in area B above lens I. The shovel returns to area A and mines lens II on the north side, leaving a ramp to the top of lens I in area B.

Step 7. The dragline mines lens I on the south side of area B, casting back to the north side for shovel loadout. Shovel ramps up to lens I, north side, area B.

Step 8. The dragline strips overburden above lens II, area B, south side, and then mines the matrix, casting back to the north for shovel loadout. After loading all of the dragline production from the south side of area B, the shovel mines out lens I, north side, area B, and ramps back down to the floor of the pit, mining out the ramp as it retreats.

Step 9. The dragline strips the overburden above lens II, north side, area B, and the shovel mines the matrix in lens II. The sequence is ready to be repeated as the shovel ramps back up on waste to the top of lens II.

laterites to expose the lower horizons of mining grade nickel ores. The separations of the horizontal layers are not always sharp and careful grade control must be exercised. This includes the removal of the lean ore or overburden occurring on the upper horizon. It may also be necessary to provide for a degree of pit perimeter layback to ensure good slope stability and safe ore mining conditions.

The overburden depth to be removed in this case will vary according to an assay cutoff for nickel. To make this selective type of operation effective, the use of motorized scrapers was recommended. The deposit has a tropical location with a well defined wet and dry season. Because of the inherent moisture of laterites, the materials cause operating problems with any type of mining equipment. When undisturbed laterites maintain stable steep slopes, but as soon as they are disturbed, they slump into a very sticky and super slippery clay mass.

Excavation and mechanical handling of wet laterite creates more than ordinary problems due to the viscous and sticky conditions. This required keeping overburden removal confined to the drier months of the year. This does not fully eliminate the handling problems, but small 10.7 m³ (379 cu ft) motorized scrapers, with front and rear drive engines,

were considered to have the necessary maneuverability to negotiate the poor underfoot conditions. Some of the deposit topography is steep, 30% or more, and the high-traction twin-powered units were considered adaptable to the conditions. The separate engine drives of the tractor and scraper make them a good tool for the wet sloppy conditions of the deposit.

Since the best laterites tend to be found on the ridges and highs, downslope pushing of the scrapers was to be done whenever possible. Erosion tends to carry away the laterite on the slopes and in the valleys. This meant that the average scraper haul for the entire life of the mine would be about 350 m (1148 ft). In the early years the haulage by scraper was maintained at one-half the average 350 m (1148 ft). Overburden waste was spread on nonore areas adjacent to the mining areas.

Scraper flexibility also permitted close grade control. The stripping depth was indicated to the operator when a calcium oxide (lime) charge, previously placed at cutoff depth, was smeared along the cut. To ensure good visibility of the cutoff mark point, overburden removal was scheduled for 12 hr per day, on two 6-hr shifts.

In addition to the eight scrapers shown in Table 10 three

* Actual experience in the same region indicated that 35.8 m³ draglines were excavating about 12.2 million m³/a in similar material.

dozers with push blocks were available to assist the twin engine scrapers.

Bauxite

A modified hydraulicking method is used by the Aluminum Co. of America (Alcoa) for removing 18 to 21 m (60 to 70 ft) of overburden from its Suriname deposit. Previous stripping methods for removing a 12 to 15 m (40 to 50 ft) highwall of material of varying consistency at up to 3.4 million m³ (4.5 million cu yd) per year had been uneconomical. Material also had to be spoiled about 11 km (7 miles) away. The stripping and transport problem led to the development of the "Double-Hinged Crawler-Mounted High-Wall Slurrifier." This machine is an open-faced jaw crusher mounted with monitors and pumping equipment on a crawler mounted platform (Koch, 1975).

Mining is done with the monitors that wash the material to the slurry sump; the crusher handles the oversize; and the slurry pumps transport the mixture to spoil using six booster pumps. Water is supplied from a lake by three 448-kW (600-hp) vertical turbine pumps. At the slurrifier unit, this monitor water is boosted to 17.6 kg/cm² (250 psi).

The pumping rate for the 25% solids slurry is 910t/h (1000 tph), powered by a 746-kW (1000-hp), 40.6-cm (16-in.) pump. Flexible 50.8-cm (20-in.) rubber lines are used to connect with 50.8-cm (20-in.) steel pipe at the slurry exit and water entry points in the pit. Normal operating kilowatts are 1790 (2400 hp) for the on-board equipment.

Overburden is removed from within a fan shaped sector outward from the slurrifier unit. Wing dams of dozed material guide the slurried bank material to the pickup point. When the radius of the fan reaches 107 m (350 ft), the setup is relocated parallel with the face.

Costs for this unit in 1982 would be \$3,000,000. This includes all on-board and remote location boosters. It is reported that in the 1981-1982 fiscal year labor was \$212,000, plus an additional \$182,000 in labor to relocate the unit and prepare the sump site. Maintenance costs amounted to \$346,000 for replacement spares and wear parts. If power is charged at \$0.05/kW/h and the operation is on a 12-hr, six days per week schedule, it is estimated that the cost for 3.4 million m³ (4.5 million cu yd) per year is \$982,000 or \$0.29/m³ (\$0.22 per cu yd). The unit is made by Hardcastle Industries, Tampa, FL.

Copper

A contemporary example of the application of hydraulic excavation is the case study of a large copper mine in the South Pacific area. Overlying much of the mine site was a layer of mainly volcanic ash, clastics material, and weathered rock. This ranged from a thin mantle to up to 61 m (200 ft) in depth, with the average being 15 m (50 ft). The entire area was covered with thick jungle vegetation. An additional advantage for a hydraulicking scheme was the steep terrain and heavy year-round rainfall.

Table 10. Scraper Design Selection

Average one-way haul	350 m (1150 ft)
Overburden output, bank	6000 m ³ /d (7850 cu yd per day)

To buy, including spares	11.0 units*

* Based on probability of having at least 8 units available 75% of the time, with up to 10 units available 20% of the time.

The contractor and owner carried out extensive hydraulicking tests to confirm viability. This work was supported by the manufacturer of the hydraulic monitor equipment. Testing was to develop design data on the following: (1) types of material that can be hydraulicked without mechanical aid, (2) mechanical assistance required, (3) areas to be included in the hydraulicking program, (4) slurry transportability vs. lump size, (5) water and monitor duty, (6) water supply data, and (7) slimes containment.

Materials to be tested by the monitor were slope wash soil and tuff and completely weathered, highly weathered, and moderately weathered rock. These initial field tests confirmed the feasibility of hydraulicking.

From the beginning of hydraulicking in April to September of the next year, production hydraulicking had removed some 15.5 million m³ (20.3 million cu yd) of mixed material types. This was at an average rate of 10 920 000 m³/a (14.3 million cu yd per year). See Table 11 for equipment for the production period.

In addition, a three-section 22.26 × 13.72 × 3.05 m (75 × 45 × 10 ft) intake structure was constructed to feed clarified water to the main pump intake. The intake stations had to be moved further upstream to avoid heavy sedimentation. This caused excessive pump and monitor wear. Normally, only three to four monitors [2.54 cm (1 in.)] operated in the ore area due to the water supply limitations.

Throughout the program, the shifts and number of people varied due to circumstances. During the first five months, the normal operation was three 8-hr shifts per day, six days per week; and then for most of the program, two 10-hr shifts per day, six days per week.

Average production in the latter period was 160 000 m³ (209 272 cu yd) per week at a rate of 138.5 m³ (181 cu yd) per dozer hour, continuously. The average water consumption was 9.1 L/s (143.4 gpm) per 1.0 m³ (1.308/cu yd). The highest rate achieved for any one hour was 213.4 m³ (279.1 cu yd) per dozer hour using 3.22 L/s (51 gpm) of

water. A low monitor water consumption was helped by the up to 50% contained water in the tuff.

Some of the conclusions reached from the production results were: (1) 40 to 50% by volume of solids optimum; (2) thicker slurries did not move well on flatter gradients; (3) grades over 4% kept the water-solids content well mixed; (4) optimum mixing of water and solids was on a -20% or more gradient, after initial water contact; (5) on gradients flatter than -5%, optimum mixing did not occur and rock buildup occurred; (6) rock buildup splits the channel flow reducing efficiency; (7) high monitor pressure in bulldozer cuts may force a slurry forward as a wave that can carry boulders to 1 m (3.3 ft); (8) average tractor push dozing was about 60 m (200 ft); (9) ground sluices at ± 10% helped decrease dozer push distances; (10) slot dozing was extensively used along with ripping where required to loosen boulders; (11) optimum monitor stream distance was 9 to 15 m (30 to 50 ft) in ground sluices.

Personnel concluded that hydraulicking was a viable proposition for removal of unconsolidated overburden.

Coal Case Studies

Of all the minerals extracted by surface mining methods, coal mining represents not only the largest industry but also the broadest range of equipment applications. Geographic variations in geology and topography have presented mine engineers with a variety of design considerations for selection of the most technically and economically sound approach to removing overburden and the exposed coal seam. While large direct casting units such as draglines and shovels represent potentially the most inexpensive means of overburden removal, mine operators confronted with rolling to steep terrain and thick multiple or pitching coal seams must resort to more mobile equipment. In these conditions loading shovels and front-end loaders working in conjunction with trucks provide viable alternatives for overburden and coal removal.

For the most part, mining practices can be characterized

Table 11. Production Equipment, Copper Case Study

No. of Items	Description
7	Centrifugal pumps, Thompson-Castlemain, 254 cm (10 in.), 157.7 L/s (2500 gpm), 198.2 m (650 ft) head at 1430 rpm. With engines pumps rated at 126.2 L/s (2000 gpm), 198.2 m (650 ft) head at 766 rpm.

regionally as a result of topographic and geologic conditions. The Appalachian coalfields including the states of Pennsylvania, West Virginia, and eastern Kentucky are characterized by rolling to steep terrain. Thus, the most common equipment applications are front-end loader/truck haulback, dozer-loader modified block cut mining, shovel/truck mountaintop removal, and small dragline modified area mining. In contrast, the topography of the midwest coalfields is flat overlying relatively thin coal seams. Surface mining in Illinois, Indiana, and western Kentucky consists of area mining with large draglines, direct casting shovels, and in one case a tandem bucket wheel excavator/shovel operation.

The western coalfields including Arizona, Colorado, Montana, New Mexico, North Dakota, and Wyoming contain the largest potential coal reserves in the nation. Topography of the entire region varies from flat plains to more rugged Rocky Mountain terrain. Where the surface is flat enough and the coal seams are thin to moderately thick, dragline area mining operations are utilized. However, the coal seams in Wyoming and Montana are often 9 to 30 m (30 to 100 ft) thick resulting in overburden coal ratios of 3:1 or less in many instances. Concentration must be placed more on the proper coal loading, hauling, and storage facilities than on overburden removal procedures. In addition, the thick seams present major spoiling problems for direct casting equipment resulting in use of open pit mining techniques for removal of overburden and coal with shovel-truck teams.

Case Study No 1: This case study describes a typical quarry type operation in a northern plains mine. The mine is situated south of Gillette, WY. This area is characterized by plains and moderately sloping hills, with land use being primarily range and cattle grazing. Rain and snow average about 30.5 to 127 cm (12 to 50 in.). The temperature will be below freezing on some 190 days and above 32.2°C (90°F) on about 20 days per year.

Coal deposits are a low sulfur subbituminous material averaging 18 608 kJ/kg (8000 Btu/lb). Coal seams range between 18.3 to 24.4 m (60 to 80 ft) in thickness and dip at about 2°. In the south, topsoil is 0 to 1.5 m (0 to 5 ft) thick and overburden 12.2 to 15.2 m (40 to 50 ft) thick. In the north, the topsoil is 0 to 1.5 m (0 to 5 ft) and overburden is 12.2 m (40 ft) of subsoil and 30.5 m (100 ft) of clays and sands. The streams and aquifers running through the area are given consideration in premining plans.

The work schedule for all operations is 3 shifts per day, 6 days per week, 52 weeks per year. Excluding 11 holidays, 903 shifts are scheduled per year. One or two shifts per year are usually lost to weather conditions.

Normally exposed coal inventories are 4.6 to 5.5 Mt (5 to 6 million st) or about 4 to 5 months production. The total overburden to coal ratio will run about 1.5:1.

Topsoil and subsoil are removed with contractor rubber tire scrapers of the 13.7- to 16.8-m³ (18- to 22-cu yd) class. The annual quantity of contractor overburden will vary but typically will be between 1.15 to 1.53 million m³ (1.5 to 2.0 million cu yd). This level of production will require a fleet of 6 to 12 scrapers with an average of 8 working. Contracts are let on a one year basis and include topsoil removal, reclamation, and contouring after mining, and placement of sands to reconstruct a subterranean aquifer removed during mining. Topsoil and subsoil are also stockpiled for long-term storage.

Overburden from the rectangular pit is hauled by 109-t (120-st) capacity, two-axle, end-dump trucks. Haulage is around the pit ends to spoil piles on the opposite highwall.

The overburden varies in thickness along the advancing highwall and stripping is normally from one to three working benches. Terraces to accommodate overburden haulage are designed around the pit ends at the level of each active bench. See Fig. 21 for an overview of mine activities. Other equipment required in the overburden removal scheme are two 22.9-cm (9-in.) blasthole drills. These drills have a 7.3 to 9.2 m (24 × 30 ft) pattern with a 1-m (3.3-ft) subdrill below grade. Drilling stops at the overburden to coal interface with all material being blasted except the topsoil and alluvium. Blasting is with ANFO at a powder factor of 300 g/m³ (18.7 pcf) of overburden. Novel trunkline and noiseless trunkline delays are used in detonation.

Excavation is by five 17.6-m³ (23-cu yd) dipper shovels. Dozers and scrapers are contractor provided with the mine providing four rubber-tired dozers for cleanup. The blasted overburden will vary per year, but will run about 15.3 million m³ (20 million cu yd) per year. Mine motor graders maintain the haul roads. The terraced overburden dump on the opposite side of the pit is dozer regraded according to the reclamation plan.

Surface stream beds that were disturbed by mining are being reconstructed with beds of sand and underlying impermeable clays. The use of sands and clays for aquifer and stream bed reconstruction necessitates some selective mining of the overburden to assure the availability of materials with the most favorable physical characteristics at the proper time. This does not pose any scheduling problems, since sands and clays are present in sizable quantities throughout the overburden.

Scrapers strip topsoil and brown subsoil from the advancing highwall, transport, and deposit them according to the reclamation plan. A 1.5-m (5-ft) thick layer of unconsolidated brown subsoil is placed uniformly over the regraded overburden followed by a uniformly thick 0.6-m (2-ft) layer of topsoil. For field use, topsoil is defined as surface material containing root medium. Topsoil and subsoil having the most favorable plant growth medium are selected on site by the reclamation department for use in land reclamation. The mining department then directs the scrapers to the areas of selected materials.

Management of revegetation operations is performed by an operating unit of the mine. It directs the placement of topsoil and the seeding with wheat of reclaimed areas. Re-seeding has not been necessary even though irrigation is not done. Artificial maintenance of reclaimed land is not cost effective.

Contour Mining—Truck Haulback Case Study: The mine is located in north central West Virginia in the Allegheny Plateau. Precipitation averages 1143 mm (45 in.) annually with temperatures ranging from -5° to 100°F. Terrain is moderately steep (greater than 25°) and covered with grasses, brush, and eastern hardwoods. This particular operation is re-affecting 33 ha (82 acres) containing old strip cuts along the Pittsburgh coal seam outcrop that ranges from 1.7 to 1.9 m (5.5 to 6.5 ft) thick. Overburden units consist of calcareous shales and soapstones with intermittent sandstone units.

Of primary consideration in selecting the basic mining approach was the existing regulations preventing downslope spoiling of overburden material and requiring restoration of the land to approximate original contour. Since the entire hilltop could not be economically mined due to excessive stripping ratios, the operator could not utilize small draglines and was forced to consider controlled placement either by dozer/loader or truck haulback operations. Preliminary

Fig. 21. Mine overview, coal case study No. 1.

evaluations indicated that a dozer/loader mine would experience difficulty with placement of the initial cut material and could not meet desired production goals. In addition, the confined working conditions and short reserve life were more conducive to mobile front-end loaders vs. quarry shovels.

The basic mining method selected for implementation (Fig. 22) is a classic example of truck haulback contour mining. Use of the mobile haulage units allowed the operator to dispose of the initial cut material on an adjoining lenticular ridge segment that had been mined prior to enactment of current stringent reclamation laws. Fig. 23 shows the disposal area with respect to the total mine site. This facilitated excavation of a 213-m (700-ft) long cut prior to initiation of concurrent backfilling activities.

As illustrated by Fig. 24, the mining plan consists of topsoil removal and storage followed by overburden drilling and blasting on 3.6×4.5 -m (12×15 -ft) centers with ANFO used as the blasting agent.

A variable powder factor is used according to the amount of sandstone encountered. Overburden removal progresses in an alternating contour block-cut method. The 10.7-m^3 (14-cu yd) rubber-tired front-end loader accompanied by a 287 kW (385 hp) dozer loads two 45-m (50-st) off-road rock trucks. Each cut is 61 m (200 ft) long with a 18 to 21 m (60 to 70 ft) highwall. Pit widths range from 29 to 37 m (95 to 120 ft). These pit dimensions reflect the past experience of the operator concerning efficient operating conditions and a maximum average stripping ratio of 12:1 [bank cubic yards (bcy) per ton].

When each cut is completed, overburden operations move to the opposite side of the initial cut to facilitate coal removal in the exposed pit. Coal is blasted with dynamite prior to extraction. One 5-m^3 (6.5-cu yd) front-end loader loads coals into 23-t (25-st) contracted coal haulers. Operations will progress in this alternating method until the hill is completely encircled.

As each mined out section is backfilled, dozers regrade and prepare areas for reseeding. Seed mixtures include Birds-foot Trefoil and Kentucky —31 fescue. Knockulate is used for a hardy first growth season cover.

With overburden removal unit operations working two 8-hr shifts per day and all other operations being performed during one 8-hr shift, the mine has produced in excess of 181 440 t (200,000 st) per year. In selecting the equipment to perform the overburden removal and achieve the desired production goals, several combinations of front-end loaders and trucks were evaluated. The loader cycle time was established at 37.9 sec from time studies at other active operations. As called for by the plan, the average round trip haul distance was 366 m (1200 ft). Utilizing these parameters, computer simulations were performed to determine the production potential, delay time, and number of trucks required for a 6.9-m^3 (9-cu yd) loader and a 10.7-m^3 (14-cu yd) loader working independently with 45- and 68-t (50- and 75-st) trucks. Narrow pit limits were deemed undesirable for larger loaders and trucks. Fig. 25, 26, 27, and 28 graphically depict the theoretical production for each combination. The 6.9-m^3 (9-cu yd) loader and two 45-t (50-st) trucks could potentially produce 5171 t (5700 st) of overburden per shift while the

Fig. 22. Case study of a truck haulback mine.

same trucks and a 10.7-m^3 (14-cu yd) loader could produce 7167 t (7900 st) per shift. Resultant economic analyses confirmed that the 10.7-m^3 (14-cu yd) front-end loader and two 45-t (50-st) trucks provided the lowest operating costs due to maximum utilization of the loader with minimum truck delay. While one 45-t (50-st) and one 68-t (75-st) truck may have improved the economics, the operator preferred to maintain a standard fleet to minimize his spare parts inventory.

Mountaintop Removal—Shovel Truck Case Study: The problems presented by this multiple seam reserve were typical of those confronting many surface mine operators considering development of a mountaintop removal operation.

Typically, mountaintop removal methods had been designed as the logical extension of contour stripping the most common practice in Appalachia. Thus, an entire mountain was mined through a continuous series of contour cuts. While this technique proved to be a viable surface mining method, there were some deficiencies:

1. Limited bench space forced haulage of a large percentage of overburden to valley fill disposal sites, imposing high haulage costs.
2. Operating costs per ton of coal mined increased as outcrop coals were depleted and advancing operations encountered consistently higher overburden to coal ratios.
3. Progressive contour lifts and requirements for large

valley fills to compensate for limited backstack space forced exposure of large surface areas for extended periods of time.

Recognizing the need to alleviate these deficiencies and maintain the total resource recovery benefits of mountaintop removal mining, cross-ridge mining was chosen by the operating company and the site was selected as a government demonstration project. Cross ridge, unlike contour methods, is designed to effect total recovery through a series of cuts perpendicular to the long axis of a ridge. This type of operation affords several potential advantages:

1. Maintains relatively consistent operating costs and production by excavating both high and low cover coal in the same cut.
2. Minimizes active mine and valley fill disturbed surface areas by creating sufficient space for overburden backstacking on the mine bench following removal of an initial cut.
3. Lowers overall mining costs through a reduction of valley fill and associated haulage requirements.

The area's topography is typical of most of southern West Virginia with steep mountains and narrow valleys or hollows. This rugged nature is evidenced by differences in elevation of over 610 m (2000 ft). Consequently, coal seams outcrop on the reserve and allow relatively easy access for mining.

Approximately 74 ha (184 acres) of minable area is associated with the cross-ridge demonstration site, containing over 2.7 Mt (3 million st) of potentially clean recoverable

coal at an average strip ratio of 6.7:1 bank cu yd (bcy) per ton. This tonnage is contained in the 5-Block and Stockton-Lewiston (site specific nomenclature) seams that average 76 mm (30 in.) and 3 m (10 ft) of clean recoverable coal, respectively. Total production from these seams had risen from 99 792 t (110,000 st) in 1975 to 428 198 t (472,000 st) in 1980. The cross-ridge demonstration contributed 171 461 t (189,000 st) from April to December 1980. However, production in 1981 experienced a sharp decline primarily due to the United Mine Workers (UMWA) strike from April to mid-June. Cross-ridge production during this 12-month period was only 70 762 t (78,000 st), while total production was 301 190 t (332,000 st).

Mining operations are separated into two working areas, each having a power shovel as its main overburden excavation unit. A 13.7-m³ (15-cu yd) P&H 2100-BL has been assigned to the demonstration project, while a 16.8-m³ (22-cu yd) BE 295-B is working in another area not associated with the demonstration. Both pits function in a similar manner with

the exception of an end-dumped fill being constructed on the demonstration site.

The first step in the mining process involves clearing and grubbing vegetation. Then two Caterpillar 657B scrapers remove the upper horizon soil material and stockpile it on a previously constructed backstack lift. Once the topcover is removed, Caterpillar D-9 and Komatsu 355 dozers prepare benches for blasthole drilling.

Blastholes are drilled on a 3.6 × 3.6-m (12 × 12-ft) spacing by four Drilltech D-40K 171-mm (6 $\frac{3}{4}$ -in.) rigs and one Ingersoll-Rand ECM-350 crawler drill. Each hole is loaded with ANFO explosive and stemmed the final 3.3-m (11 ft). When overburden above the 5-Block seam is blasted, dozers push material over the highwall by a slot method. On a bench below, two Dart D600C front-end loaders load the spoil into Euclid R-35 and R-50 off-highway trucks for transport to on-bench backstack areas. Caterpillar D-8 dozers spread and compact the material into the 15-m (50-ft) lifts.

To ensure a clean marketable raw product, the final 0.6

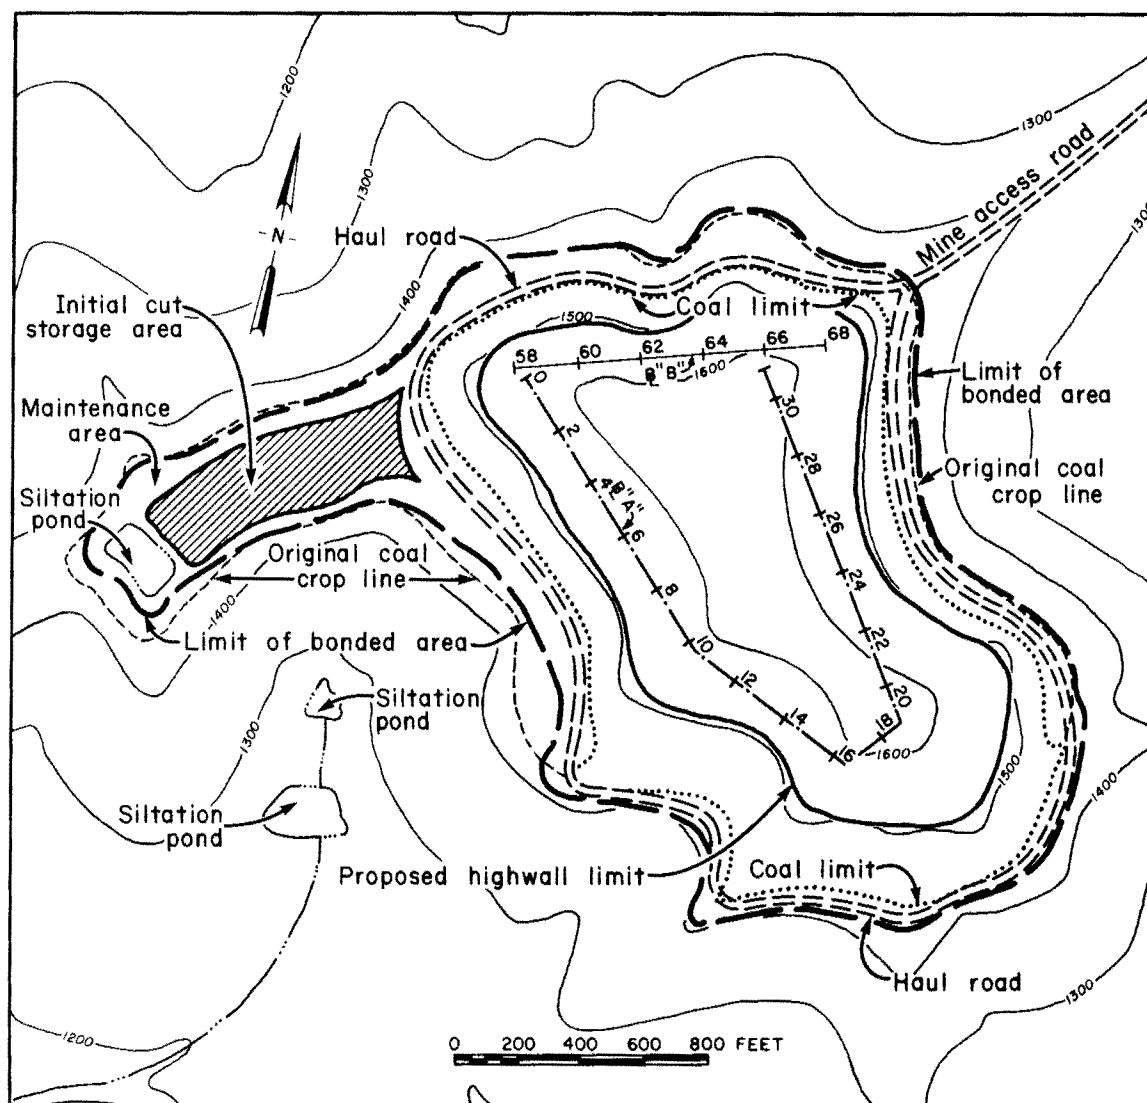

Fig. 23. General location map of mining area, truck haulback mine, showing disposal area in relation to the total mine site.

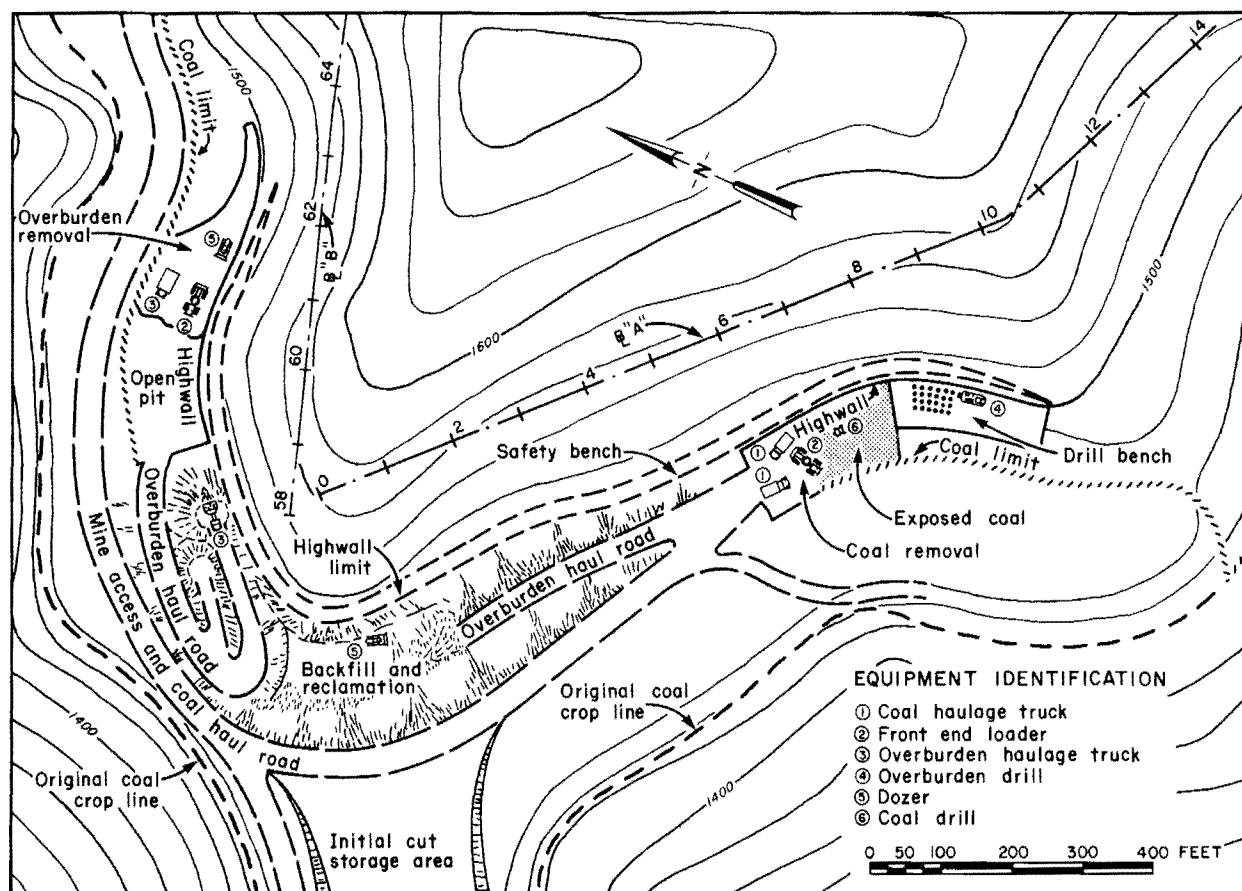

Fig. 24. Truck haulback mine layout plan map.

to 0.9 m (2 or 3 ft) of overburden is removed from the 5-Block seam by a Caterpillar 992A loader, and the coal is cleaned by a tractor-mounted rotary broom. Coal is then loaded via Cat 992C and Cat 992B end loaders onto trucks for transport to the central loading station away from the permit area.

After the 5-Block seam is removed, drilling and blasting is performed on the sandstone interburden above the Stockton-Lewiston seam. Holes are drilled on a 4.9×4.9 -m (16

\times 16-ft) spacing to within 6 m (20 ft) of the Stockton-Lewiston. The hole depth averages 23 m (75 ft) with 6 m (20 ft) of stemming added after loading the ANFO. Fragmented sandstone overburden is loaded and transported to the valley fill or backstack area by the two electric shovels and a fleet of rock trucks including ten Euclid R-105 and five Dart 3100 vehicles. Records from the demonstration indicate that the P&H 2100-BL places three dipper loads per truck at a bucket fill factor of 90% (see Fig. 29). The shovel

Fig. 26. Equipment delay time/production graph for a 68-t (75-ton) and one 6.9-m^3 (9-cu yd) loader system.

Fig. 27. Equipment delay time/production graph for a 68-t (75-ton) truck and one 10.7-m³ (14-cu yd) loader system.

Fig. 28. Equipment delay time/production graph for a 45-t (50-ton) truck and one 10.7-m³ (14-cu yd) loader system.

has experienced an 85% mechanical availability and an average of 38 sec per cycle. With trucks hauling an average one-way distance of 518 m (1700 ft), the shovel produces 190,000 bcy per month during normal operations.

The 6 m (20 ft) of overburden remaining above the

Stockton-Lewiston seam is usually mined by the shovels as a second lift. This material is a mixture of sandstone and shale and requires blasting prior to loading. The location of spoil placement depends upon material composition. Only durable sandstone is placed in the demonstration fill.

Fig. 29. Shovel truck loading at a mountaintop removal operation.

As in the final excavation over the 5-Block seam, the last 0.6 or 0.9 m (2 or 3 ft) of overburden above the Stockton-Lewiston is removed by front-end loader. The coal surface is also swept by the rotary broom. Because of partings, the seam, as depicted in Fig. 30, is removed in three lifts. The top and bottom lifts are of high quality, while the middle split must be blended with the better coal prior to sale.

The cross-ridge mining system has received an added economic benefit due to incorporation of the durable rock end-dumped valley fill. Approved by the Department of Natural Resources (DNR) under an experimental variance, this fill represented major changes from the standard West Virginia construction procedures, including:

1. The fill is being constructed from the head of the hollow as compared to beginning at the toe (see Fig. 31).
2. All material is being dumped from the Stockton-Lewiston bench vs. hauldown by rock trucks.
3. The final fill face will be terraced on 15-m (50-ft) benches rather than construction of 15-m (50-ft) benches with compaction in 1.2-m (4-ft) lifts throughout the fill area.
4. External drainage is diverted to side ditches vs. the West Virginia procedure requiring direction of all drainage to a central rock chimney drain.

Since the fill must contain 80% durable rock (the Standard Slaking Test is acceptable to the DNR) by volume, most of the 1.1 million m³ (1.5 million cu yd) of material placed in the fill to date has come from the interburden between the 5-Block and Stockton-Lewiston seams. This durable sandstone unit has facilitated achievement of a stable fill and, through natural segregation, development of an 2.4-m (8-ft) underblanket for drainage. When completed the fill will have allowed permanent disposal of 5.9 million m³ (7.8 million yd³) of excess spoil material.

Costs and productivity have been documented thoroughly for the P&H 2100BL shovel and Dart 3100 trucks. Considering an average haul distance of 518 m (1700 ft), the shovel/truck team has averaged approximately 560 bcy per operating hour. Three trucks have provided an efficient match, keeping the 11.5-m³ (15-cu yd) shovel productive. Examination of only basic direct costs (Table 12) associated with the shovel/truck team reveals a cost of \$0.74 per bcy.

Fig. 30. Columnar section, Stockton-Lewiston coal seam.

For comparison, construction of a West Virginia style fill would have resulted in an additional 1585-m (5200-ft) hauldown, increasing the average round trip cycle time including load/dump from 8 to 16 min. Operational plans would have required three additional trucks to maintain the P&H 20s present hourly production level. The resultant cost per bank cubic yard would have been \$1.13. With an average stripping ratio of 6.7:1, the end-dumped valley fill has produced a minimum savings of \$2.60 per ton. Factoring in overhead, benefits, and other operational costs, including added wear and higher maintenance costs on the trucks, even greater savings have been realized. While these savings will decrease as the fill approaches completion, the impact in terms of present-day dollars is extremely important to the life of mine profitability.

Area Mining — Dragline Case Study: The mining site under study is located in the midwestern coalfields. Topography is characteristically flat to gently rolling, with cropland cover and agricultural land use. The overall mine area is approximately 648 ha (1600 acres).

Two coal seams are present and considered of minable thickness and marketable quality. Overburden and interbur-

Fig. 31. Profile of end-dumped valley fill.

Table 12. Basic Direct Cost Associated with Shovel/Truck Team

Unit	Depreciation	Fuel/ Power	Lube	Tires	Parts/ Supplies	Labor	Total
11 m ³ (15 cu yd) shovel	\$84.36	\$31.40	\$20.14	\$ —	\$35.61	\$22.00	\$193.51*
90-t (100-st) trucks	\$22.14	\$ 9.07	\$ 4.33	\$16.88	\$11.12	\$10.31	\$ 73.85*

* Direct cost per bank cubic yard per operating hour.

den at the site total approximately 38 m (126 ft). Cover above the upper seam consists of 1.2 m (4 ft) of topsoil, 3.7 m (12 ft) of unconsolidated subsoil, 12 m (40 ft) of shale, 5 m (18 ft) of clay and sandy shale, and 9 m (31 ft) of sandstone directly above the 1.2-m (4-ft) thick upper seam. Interburden down to the lower 3-m (10-ft) thick seam consists of 6.4 m (21 ft) of sandy shale. Both seams are flat lying and maintain a consistent thickness throughout the mining property. The raw recoverable reserves are approximately 28.6 Mt (31.5 million st) for the composite seams.

Based on the general site information, it was determined that the reserve site was particularly suitable for development as an area mine. Both overburden and interburden are mined with a large dragline, utilizing a simple sidecast technique on the upper seam and a less efficient chop-down technique from the spoil side on the lower seam. However, to comply with federal requirements for topsoil handling in prime farmland, a separate system was needed to remove and segregate 1.2 m (4 ft) of A horizon and 3.7 m (12 ft) of combined B and C soil horizons. Due to the need to transport and stockpile a minimum of three cuts of topsoil and subsoil prior to replacement, scrapers were selected for this operation.

The virgin stripping ratio for the mine is 9:1 (bcy/ton). Annual coal production was projected for approximately 1.4 Mt (1.5 million st) per year, which would result in achievement of a 20-year mine life. This production level was consistent with market requirements and provided for a 20-year depreciation of the dragline purchase.

With a knowledge of the production rates required and all other site information, the equipment selection was made to best meet these parameters. Assuming that the top 4.9 m (16 ft) of cover would be removed as a separate operation, the choice of a dragline was made on the following criteria:

1. Minimum cut width of 32 m (105 ft), 30% swell factor, 75° highwall angle and 34° angle of spoil repose.
2. Based on its range diagram, the dragline had to have an operating radius of at least 90 m (295 ft).
3. It had to have a capacity of digging to a depth of 34.7 m (114 ft).
4. Considering the stripping ratio and approximately 10% rehandle, the bucket size had to be of sufficient capacity to meet the production requirements in both the simple sidecast and chop-down techniques.

Several manufacturers' specifications for draglines were examined to meet these conditions. This review revealed that a 2570-W dragline with 72.6-m³ (95-cu yd) bucket and a 94-m (310-ft) boom at 30° would meet the requirements. Following are the production factors utilized in selecting the dragline as well as the scrapers and drills.

Bucyrus-Erie 2570-W Dragline

- 1) Bucket size 72.6 m³ (95 cu yd)
- 2) Fill factor, 90%
- 3) Cycle Time, + 63 sec
- 4) Job efficiency, 89%
- 5) Capacity per hour: (1) simple sidecast seconds 3106

bcy per hr @ 100% availability; (2) chop-down method = 1398 bcy per hr @ 100% availability

6) Mechanical availability = 85%

7. Job efficiency = 87%

8. Capacity per hour = 91 bcy per hr @ 100% availability

9. Mechanical availability = 75%

Following removal of the topsoil and subsoils, the selected mining method was implemented by excavating an initial cut across the entire width of the mine. This cut provided an open face for all future cuts perpendicular to it and provided access for coal removal. Upon completion of the first cut, the dragline opened a second box cut perpendicular to the first. After exposing the first seam by sidecasting, as shown in Fig. 32, the dragline walks down the spoil side of the cut on a bench that has been prepared by leveling or filling and exposes the second seam, as shown in Fig. 33 by using a chop-down technique. The dragline alternates between these two operating modes until the 2438-m (8000-ft) cut is completed and the subsequent parallel cut is ready for excavation. Working three shifts per day, 341 days per year, the dragline produces in excess of 14 million bcy per year.

Prior to dragline excavation, the overburden is drilled and blasted utilizing two B.E. 60-R drills. The 31-cm (12¼-in.) holes are spaced at 7.9 × 7.9 m (26 × 26 ft) with 0.6 kg (1.3 lb) of ANFO employed per bank cubic yard of overburden.

Coal loading operations are conducted on a one shift per day basis at a safe working distance behind the dragline operation. A 12-m³ (16-cu yd) shovel loads the coal into five 145-t (160-st) bottom dump coal haulers for transport to the tippie.

Regrading of the area is accomplished by bulldozers that cap and fill dragline spoil piles. Following storage of topsoil from the initial cut and the first three regular cuts, topsoil is directly replaced on graded spoil by the scrapers. Thus, concurrent regrading and reseeded is accomplished enhancing reclamation potential.

FRED R. SARGENT

HISTORY AND DESCRIPTION OF EXCAVATORS

Henry Rumfelt in the first edition of *Surface Mining* presented the general history of cyclical machines used in excavating in surface mines. It will be helpful to review part of that material before proceeding.

The history of excavating machinery is not clearly defined but the machines seem to have been originally developed for dredging activities, principally involving rivers and harbors. The first, as far as can be determined, was a steam "spoon dredge" developed by Grimshaw of Boulton and Watt of Sunderland, England, in 1796. The land machine forerunner of the present-day power shovel was not developed until 1835. It was invented by William Smith Otis, a young partner of a Philadelphia contracting firm by the name of Carmichael and Fairbanks. The moving force behind this invention was the heavy activity in railroad construction. (See Fig. 1.)

From this early start, the power shovel has developed from steam powering to internal-combustion-engine powering and to electric powering. In both directions, it has developed to its present state of a finely engineered and precision-built tool. Through the interim, the railroad-type shovel, about a half-swing arrangement designed especially for making railroad cuts and mounted on rails, was developed. The rail-mounted shovel gradually gave way to the full revolving shovel. It was high on the list in 1912 and was practically extinct by 1927. From the beginning, a few of the small revolving shovels designed primarily for the general contractors' market had found their way into quarry and mining operations.

During this same period, the *stripping* shovel had been introduced—a 1.9 m³ (2.5 cu yd), 90-t (100-st), full revolving stripping machine with a 12.5 m (41 ft) boom. Although this shovel was designed especially for stripping, it was also used for heavy-duty, open pit mining service. In 1925, the heavy-duty full revolving quarry and mine machine was developed.

Strip mining shovels evolved through a somewhat separate path. Hand-digging plows and mule-drawn slip scrapers were first reported used by Kirkland, Blakeney and Groves near Danville, IL, for strip mining coal. In 1877, Hodges and Armil used an Otis-type steam shovel in stripping a property near Pittsburg, KS. In 1855, Wright and Wallace used a wooden dredge with wheels applied for land mobility for coal strip mining near Danville, IL. The machine was equipped with a 15.2-m (50-ft) boom.

The first true *stripping* shovel began work in 1911 in the Mission Field just out of Danville, IL. The machine had a 19.8-m (65-ft) boom, 12.2-m (40-ft) dipper handle, and 2.73 m³ (3.5 cu yd) dipper. It was steam-powered and propelled on four four-wheel bogies, which in turn ran on rail tracks. It operated in 6 to 9 m (20 to 30 ft) of shale and gravel overburden uncovering 2 m (7 ft) of coal. Electric powering came into the picture about 1916. Ward Leonard Electric powering came later and has continued to be the basic system of powering through the present.

Hydraulic leveling jacks were introduced early and have become standard on all *stripping* shovels. Special features such as counter-balanced hoist, bridge strand-type boom suspension, wire rope crowd, and "knee-action" front have all been introduced, and some of these are used on the modern *stripping* shovel (Fig. 2).

Fig. 1. An early excavator, Barnhart's steam shovel.

Fig. 2. World's largest stripping shovel Marion Model 6360 with 138-m³ (180-cu-yd) dipper.

Evolution has produced nomenclature that indicates the *mining shovel* to be a machine mounted on only two crawlers, while the *stripping shovel* is mounted on four sets of crawlers each having two crawler belts placed side by side, thus the term eight crawler machine used to denote a stripping shovel.

The digging element of a power shovel is a dipper attached to a handle. The dipper lip, the principal cutting edge, is attached to the dipper front and is equipped with replaceable teeth. The handle is connected to the back side of the dipper. The dipper bottom is a hinged door and has a latch for dumping the contents.

In operation, the dipper is pulled through the bank by hoist cables and, on the modern type, is held against the bank by the crowd motion which extends or retracts the handle lengthwise. The handle is pivoted about a fixed point, and it is positioned lengthwise by crowd motion; and the dipper is pulled through the cut. When the dipper is full, the machine swings sidewise and the dipper load is dumped through the door.

The entire machine is usually mounted on a system of crawlers. The crawlers are endless belts of links hinged or pinned together. They permit mobility and the positioning of the machine with respect to the bank.

Electric energy is furnished to the machine through a trailing cable and usually powers a large motor-generator set with multiple generators. In the full Ward Leonard system, each generator furnishes d-c power to separate motors which drive the principal motions of the shovel: hoist, crowd, and swing. By the use of such devices, shovels of remarkable performance, speed, and smoothness have been developed primarily for these surface mining activities.

Similarly the history of the hoe is not clearly defined. Patents as early as July 17, 1855 (E.O. Rood) describe a dredging apparatus which uses a digging motion involving a boom and handle that is directed toward the machine. Later on there were land-mounted machines. However it was not until about 1925 that the device became quite popular.

The name describing the device has gone through an evolution. It has been described by many names such as "backhoe," "drag-shovel," "back action," and "pull-shovel." Now, however, the trend is to call it a "hoe."

The main advantage of the machine is its ability to dig below itself with a positive action. It has been used in trenching and basement excavation for domestic dwellings.

While the history of *dragline* excavators is not nearly so defined as that of shovel equipment, early dragline models used dragline booms on excavators in the early 1900s. Dragline booms were applied to crawler excavators to extend the excavator's reach and to dig into wet areas or areas that would not support the shovel's tracks.

The first walking dragline as it is presently known was patented by Oscar J. Martinson of the Monaghan Manufacturing Corp. This company eventually became part of the Bucyrus-Erie Co. Another early manufacturer of walking draglines was the Page Engineering Co. of Chicago, IL. Marion Power Shovel entered the walking dragline business in the 1930s. The first walking draglines were built with essentially the same equipment as the shovel but without the lower frame and crawlers of shovel equipment. Instead, the crawlers were replaced with a tub upon which the machine sits. The shoes or pontoons at the side of the machine are attached to the revolving portion of the dragline, and when the machine walks, the shoes lower themselves to the ground and the eccentric device attached to the shoes elevates the machine and slides it backwards. This process is then repeated after the shoes leave the ground again and the machine thus walks its way to its new digging location.

Early dragline excavators generally were less powerful machines than the shovel excavator, both from a connected horsepower standpoint and the fact that the dragline relies on pulling the bucket through the ground, whereas the shovel excavator is directly connected to the dipper and is both pulled and forced through the earth by a rigid connection to the dipper.

Dragline excavators originally were utilized in moist or wet conditions where the low-bearing pressure of the tub would allow the machine to propel on top of the ground while digging below its tub and in stripping conditions where blasting was not required or was minimal. Early dragline excavators became known as excavating tools for digging "easy" material, whereas the shovel excavator was generally used in the harder or blasted materials. The evolution to the

use of the dragline in rough, broken rock took many years and was brought about generally by better blasting practices and materials, as well as better tools for drilling of the ground itself and higher horsepower in the dragline. The most important feature of draglines, however, was their ability to dig deeper overburden depths than the stripping shovel could effectively handle. Often these draglines were used in conjunction with a shovel wherein the dragline excavator would take the top portion, or soil above the rock portion which would have to be blasted. The blasted portion of the overburden would then be removed with the shovel excavator.

From the first draglines utilized in the mining industry until the early 1960s, the largest walking dragline was a machine with 68.6 m (225 ft) of boom coupled with a 26.8-m³ (35-cu yd) bucket; this size machine had been continually produced from the early 1940s. Thus from 1900 to 1940, the industry went from 1.5 or 2.3 to 11.5 m³ (2 or 3 to 15 cu yd). From 1940 to 1960, the size of draglines increased from 11.5 to 26.8 m³ (15 to 35 cu yd). During the 1960s the era of the super dragline was to take rapid hold in the mining industry. When it was sold in late 1960, the Marion 7900 with 83.8 m (275 ft) of boom and a 30.6-m³ (40-cu yd) bucket was the world's largest dragline. By 1969, when the Bucyrus-Erie 4250W went to work with its 94.5-m (310-ft) boom and 168.2-m³ (220-cu yd) bucket, the industry had increased dragline size fivefold in less than ten years (Fig. 3).

While only one of these 168.2-m³ (220-cu yd) dragline excavators has been produced, approximately 50 walking draglines of the 76.5 m³ (100 cu yd) size and larger are currently working in mining operations through the free world. The average size of draglines sold has doubled during the last decade.

REVIEW OF DEVELOPMENTS IN CYCLICAL EXCAVATING EQUIPMENT, 1968-1983

Rumfelt and Boulter in the first edition of *Surface Mining* (1968) gave various developments that had occurred up until that year in the excavating machinery business. Developments in the ensuing 21 years have been numerous and can best be described by commenting on these by the type of machinery.

Mining or Quarry-Type Shovels

The trend to larger two-crawler machines has accelerated with the advent of haulage trucks driven by electric wheel motors. In 1968, 11.5-m³ (15-cu yd) shovels and 90-t (100-st) trucks predominated. Marion Power Shovel in the early 1960s built two 291M two-crawler machines (Fig. 4) capable of utilizing 19 to 26.8-m³ (25 to 35-cu yd) dippers; however, truck sizes were too small and the machines were used only for stripping overburden in coal. Harnischfeger Corp. in 1982 built a Model 5700 (Fig. 5) with a 45.9-m³ (60-cu yd) dipper for loading trucks. Now, as in 1962, economical truck size has not kept pace with shovels.

Harnischfeger was first to market static power conversion for electric mining shovels, thus eliminating the rotating motor generator sets and replacing the generator with thyristors. Initial problems of all manufacturers with statics were with low power factors, fuse protection, cooling of the thyristors, and troubleshooting. These problems have now been eliminated.

All manufacturers of electric mining shovels now design propelling systems that utilize motors and gearing on the lower works in their larger shovels from 9.2 m³ (12 cu yd) and upward in size. This system eliminates maintenance on

Fig. 4. Marion 291M mining shovel.

the gearing and shafting from the revolving frame down to the lower works.

Other innovations in mining shovels include a trend toward increased cutting efforts by the combination of higher hoist and crowd horsepowers and front-end geometry, dual motor propel systems, and design of modular components for the reduction of shovel downtime.

One innovation on the market is the Marion 204M SuperFront mining shovel which utilizes a radical departure

in front-end geometry. A pitch system allows a flat pass and greater cutting effort vs. the conventional shovel front end. The machine utilizes a nominal 24.5-m^3 (32-cu yd) dipper (Fig. 6).

Hydraulic Excavators

If there has been any revolution in excavators, it has been in the introduction of large, heavy-duty hydraulic excavators into mining operations. First developed by German manu-

Fig. 5. 46-m^3 (60-cu-yd) class coal loading shovel. P & H Model 5700.

Fig. 6. The 24-m³ (32-cu-yd) SuperFront mining shovel with its unique front-end geometry.

facturers as small construction machines, the larger hydraulic shovels and backhoes have created a market which can be classified between electric shovels and front-end loaders.

During the booming mid-1970s, hydraulic excavators were readily available, whereas electric shovels were not, due to backlogged plants, and this shorter delivery coupled with faster erection time brought the hydraulic excavator into mining. Thus the hydraulic excavator made inroads into mines and new mining ventures. The largest usage of hydraulic excavators is in quarries and coal mining where digging conditions are easier than in metal mines. They are being utilized as both stripping excavators loading trucks and also as coal loaders, both in front shovel and backhoe configurations.

While hydraulic units up to 23 m³ (30 cu yd) have been manufactured, the 7.6 to 17 m³ (10 to 22 cu yd) are the most popular sizes (Fig. 7).

Since initial hydraulic excavators in mining were adaptations of construction machines, three-shift, seven-day-per-week applications caused low availabilities and high costs. Newer units are more rugged and have shown higher availabilities even with high utilization common in mining excavators.

Both diesel and electric driven machines are available and have essentially replaced smaller diesel and electric cable shovels.

Due to the lack of large hydraulic motors, rugged mine conditions in large volume metal mines, and lack of mine technicians trained in high pressure hydraulics, it is doubtful that in the near future hydraulic machines will entirely replace the dependable electric cable shovel with its low unit cost capabilities.

Stripping Shovels

The last stripping shovel (eight-crawler machine) sold was a Marion 5900 in 1969, and while these workhorses of the US coal mining industry continue to operate removing overburden in the midwestern US coalfields, the trend away from these large shovels continues. Walking draglines have replaced the shovel due to deeper coal overburden depths, multiple coal seams in the same field, and greater flexibility with the dragline. Because the stripping shovel operates in the pit, it has limited depth capability.

No new developments from either Bucyrus-Erie or Marion Power Shovel indicate that, unless some new market should develop, the era of the stripping shovel is dead and

the machines now working will eventually be scrapped as their dedicated coalfields work out.

Walking Draglines

From 1968 to 1989, large walking draglines have largely been modernized by changing various features of the machines to provide greater mechanical availability of the machine. Walking systems and booms have been improved, and better methods of monitoring both production and problems have been established. Improved weld criteria, metallurgy, and design features have been instituted by the manufacturers to help operators increase uptime. Size ranges in 1968, while primarily up to 45.9 m³ (60 cu yd), have jumped up to 76.5 to 84 m³ (100 to 110 cu yd) in 1989 with a preponderance of 45.9, 57.3, and 84 m³ (60, 75, and 110 cu yd) machines working. Only six draglines in the free world have bucket capacities over 88 m³ (115 cu yd). Yet approximately 250 draglines are working or scheduled with bucket capacities of 42 to 88 m³ (55 to 115 cu yd) (Fig. 8).

Draglines are now working multiple seam operations vs. primarily single seams 15 years ago. Extended bench, spoil side stripping, and other dragline techniques have produced ways for operators to utilize this lowest-unit-cost machine in areas previously not indicated as being applicable.

In the smaller walking draglines, manufacturers have designed modular quick erection and teardown machines for use in smaller deposits of mineral. In addition, static power conversion systems are utilized as in electric mining shovels, thus eliminating motor generator sets for conversion of incoming a-c power to d-c for motion drive motors.

Crawler Draglines

Neither design nor utilization of crawler draglines has changed appreciably since 1968. Smaller coal mining operations are the primary users, along with bauxite, lateritic nickel, and small phosphate operations. Construction materials quarries, such as coral rock and sand and gravel, also utilize crawler machines.

The larger units for mining now reach boom lengths of 78 m (255 ft) and bucket capacities of up to 16.8 m³ (22 cu yd), Fig. 9.

Backhoes and Clamshells

Backhoe excavators in 1968 were primarily cable type, with limited usage in the mining industry. Recent machines are entirely hydraulic with respect to the front-end structure and have found more acceptance in coal loading where the

Fig. 7. A typical 11.5-m^3 (15-cu-yd) class hydraulic front shovel in a coal operation.

backhoe can sit on top of the coal and load the truck on this same level, thus keeping both machines out of wet or mucky conditions. In some applications, the backhoe sits on top of the mineral and loads the truck which sits on the bench below it at the bottom of the mineral (Fig. 10). Cycle times are less in this instance.

Clamshell excavators are essentially draglines fitted with clamshell buckets and different rigging of the hoist and drag ropes to perform opening and closing of the clam bucket. Other than below waterline digging of coral rock, rehandling and dredging construction projects associated with mining, there is little use of large clamshells in mining (Fig. 11).

MINING AND QUARRY SHOVELS

FRED R. SARGENT

Fig. 9. Large crawler dragline P & H Model 2355.

Machine Features—Mechanical

The basic mining shovel and its components are illustrated in Fig. 12. A deck layout of a shovel is shown in Fig. 13. The main mechanical parts of the shovel are: crawler side frames which bolt or weld to the lower frame or carbody; the revolving frame upon which are mounted the swing and hoist machinery and major electric drive components; the boom, which generally has the crowd machinery attached; and the dipper handle and dipper. A gantry and suspension ropes to hold the boom in position and a covering or house over the machinery and electrics comprise the remainder of the machine.

The mining shovel is a rugged, heavy-duty machine designed to take the abuse imposed on it from continual digging forces and shock applied by the motor torques which drive the dipper into and upward through the digging face. With proper maintenance, these machines can work 24 hr per day, 7 days per week.

Propelling machinery, including motor(s), is either mounted on the carbody or driven by the hoist motor through shafting and gearing from the revolving frame. The final gear reduction boxes are connected to the crawler side frames to provide propelling of the machine.

Each motion of hoist, swing, crowd, and propel is driven by a heavy-duty high-torque, low-speed motor or motors which are required for high production at minimum cost.

Fig. 10. A typical backhoe.

Fig. 11. Barge-mounted clamshell.

Fig. 12. Exploded view drawing of a typical mining shovel.

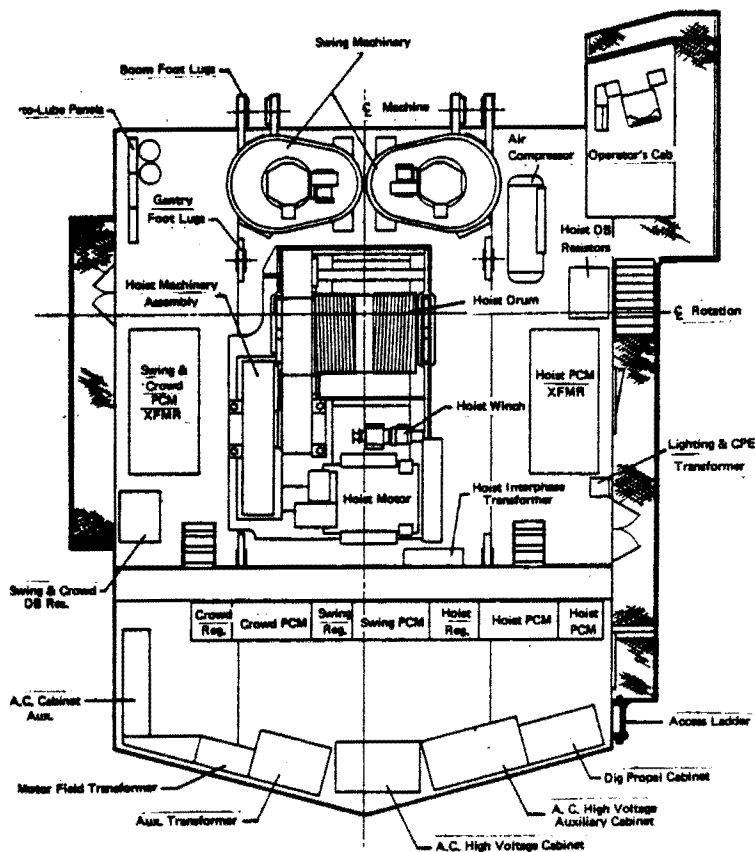

Fig. 13. Deck layout of a typical mining shovel.

The propel motion will drive the machine forward or backward at an approximate speed of 1.6 km/h (1 mph). Large shaft or motor brakes hold the machine in position when digging.

The swing motion is driven with two or four independent sets of gear reductions; the motors are connected together electrically to provide high swing torque for fast acceleration and deceleration. Since the mining shovel is generally loading trucks or railcars, and only swings 90°, fast response is important for good cycle time.

The hoist machinery is powered by adjustable voltage motors (dc), adjustable frequency motors (ac), or eddy current slip coupling. The eddy current unit consumes more power than an adjustable voltage motor. The final hoist gear reduction connects the motors to the hoist drum. Wire ropes attached to the drum are reeved over the boom point sheaves and connect to the dipper bail or dipper. The hoist gear ratio is selected to provide optimum dipper force and speed for most digging conditions.

The crowd motion is to position the dipper into the bank, allowing a narrow or deep slice to be made. The shovel operator can control the crowd so the hoist motion does not stall and yet fills the dipper. The crowd or dipper handle can be driven by means of a rack and pinion or by wire ropes.

The shovel dipper itself provides the most controversy among operators. Depending on material weight, fragmentation, and toughness, as well as abrasion, the dipper can be heavy duty, medium duty, or light duty. Generally the heavier dippers are constructed of cast manganese alloy, with the lighter dippers of fabricated wear resistant alloys. Heavy duty

taconite dippers weigh approximately 2373 kg/m³ (4000 lb per cu yd) while coal loading dippers weigh about 1186.6 kg/m³ (2000 lb per cu yd). Manufacturers tend to supply medium weight dippers of 1780 kg (3000 lb) or less for medium to hard digging. Dippers are sized to provide the maximum load for each application. Truck size, bank height, material fragmentation, and abrasiveness are all considered in order to minimize dipper maintenance and power consumption.

Shovels are generally built with standard length booms and handles for loading haulage units on the same level as the shovel. However, medium and long-range booms with smaller dippers can also be utilized for stripping machines and for loading units on benches above the shovel.

Machine Features—Electrical

Larger solid-state rectifiers have converted the electric mining shovel in sizes above 11.5 m³ (15 cu yd) from Ward Leonard motor generator set machines to static power conversion electrics. The current shovel is supplied a-c incoming power at different voltages depending upon location, and this power is converted to d-c or a-c (power) for motor motion by static controlled thyristors or rectifiers. Shovel response is excellent and repairs to the large generators are eliminated. A typical one-line diagram of the electrics is shown in Fig. 14.

The motion control motors can be either dc or ac and the characteristics, advantages, and disadvantages of both are shown in Fig. 15. For variable frequency a-c motion motors, because incoming mine power is ac, the power must be converted to dc and back again to ac to provide the ability

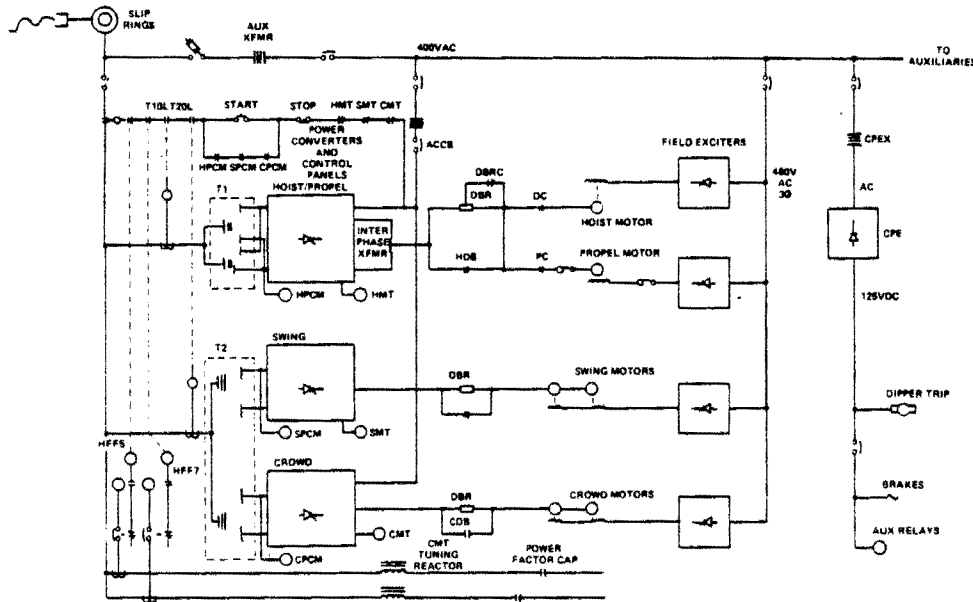

Fig. 14. A typical one-line diagram of electrical system for a mining shovel.

to vary frequencies. This additional rectification causes a certain power loss and adds to the complexity of the system. Certain motor advantages are claimed, however, such as lack of brushes and commutator wear in the a-c motor system.

A standard construction d-c mill-type motor used on excavators is shown in Fig. 16. The motors are adjustable voltage (speed) motors. They are built for fast reversing on

a constant basis and have a split frame for easy removal of the armature. These motors are available in 44.8 to 969.8 kW (60 to 1300 hp) at 475 V, the normal rating voltage, with peak power of 67.1 to 1417.4 kW (90 to 1900 hp) at peak voltage of 575 V.

Incoming a-c power to mining shovels is normally 4160 or 7200 V at 60 Hz in the US and 6600 V at 50 Hz in most

Fig. 16. A standard construction d-c mill-type motor.

foreign countries. Power supply is critical to good shovel operation and shovel manufacturers prefer voltage fluctuations to be limited to $\pm 10\%$ of the nominal voltage. Trailing power cable to the shovel is three conductor SHD type with a ground conductor.

Static power conversion shovels using conventional converters have inherently poor power factors and must be corrected by using switching capacitors or a newly designed four-legged bridge where phase to neutral connections can be utilized to improve the power factor. Static power converters generate harmonics that must be filtered out.

Newer static systems utilize microprocessors and digital systems for both control of the system and diagnostics of problems in the system itself. Analog systems are in use by some manufacturers.

Application and Use of Mining Shovels

Mining shovels are utilized in many different types of operations, but the largest users are in copper, iron ore, coal

stripping, and uranium. Stripping and mining which move large tonnages on a daily basis rely on mining shovels as their prime movers coupled with haulage trucks in the 77 to 213.2-t (85 to 235-st) class. A generally accepted rule is that three to five dipper loads will fill the truck. This limits the truck idle time under the shovel to a minimum. The cost per hour for a large truck is generally close to that of a large shovel and there are many more trucks than shovels in an equipment fleet. The large haulage truck of today must be kept productive; time under the shovel and waiting time are the largest units of nonproductive time in the cycle.

Balanced against truck and shovel sizing, however, is the problem of having sufficient shovel units in the pit to be able to blend various grades of ore encountered and to keep sufficient benches opened to assure ore for the concentrator operations. This is particularly true for metal mining operations.

Considerations in determining shovel size include the following: pit floor strength (ground bearing pressure), truck size, bench height, tonnage required, blending required, number of ore and waste faces required, fragmentation expected, maintenance facilities, infrastructure requirements, weights of material, pit geometry, dipper weight required, and future possibilities in all these items.

Figs. 17 and 18 show typical shovel loading operations at coal stripping and metal mining operations. Fig. 19 shows a range drawing for a typical 25-yard-class shovel.

In recent years the trend has been not only to larger shovels in the 13 to 26.8 m³ (17 to 35 cu yd) range, but also in utilizing shovel/truck fleets to prebench ahead of large stripping draglines as deposits of coal become deeper. In many multiple-seam coal operations, draglines cannot be easily utilized and shovel/truck combinations become the major equipment application.

Due to increasing costs of oil and diesel fuel, the trend to full electric shovels continues. Full-diesel shovels and diesel-electric versions are declining and are virtually unused except in small operations where power line construction is uneconomical and where mine life is comparatively short.

Productivity and Costs

The element most consistent in surface mining is inconsistency. No two mineral deposits are the same and this can be said for production rates and costs of shovel equipment. When estimating, however, it is important to utilize a con-

Fig. 18. A typical mining shovel loading operation in a metal mine. Marion Model 191 m.

sistent approach to the factors used. For more details on definitions for hours utilized, bank vs. loose yards, fill and dipper factors, etc., refer to the section on draglines.

Material in situ has a certain specific gravity and is utilized as the starting point to obtain shovel production rates. Next a swell or swell factor is applied to give a loose weight after blasting or loading. The dipper fill factor (percent of struck capacity) gives the volumetric equivalent of the material as compared with the volume of the dipper.

Fill factors of dippers range from 40 to 50% for heavy blasted rock and are up to 120% for loose lighter weight alluvial materials. Generally, 85% fill factor is normal for overburden materials that are well blasted.

Mining shovels have cycle times that vary from 22 to 35

sec, depending on swing angle, material weight and preparation, and operator skill. The longest percentage of time is spent swinging—about 60% of the cycle. The average time for swing both ways in a typical 90° swing is 18 to 20 sec. Hoisting or digging time will vary greatly depending on material being loaded, but 6 to 8 sec is normal. Dumping time is approximately 2 sec. A typical production calculation is shown in Table 1.

While the theoretical ability of the shovel to produce can never be utilized in actual practice, mine operators can keep productivity high by reducing maintenance time on shift and improving truck scheduling to the shovel. Shovel production rates for various sizes of machines are shown in Table 2.

Actual cost figures for electric mining shovels depend on many factors such as the accounting system, labor rates, mine conditions, etc. Some general rules commonly used to estimate cost are:

Power costs will run from 0.15 to 0.25 kWh per st moved (0.3 to 0.5 kWh per bank cubic yard).

Maintenance labor, supplies, lube, oil, parts, etc., will run 10 to 15% of the installed cost of the machine per year, depending on digging conditions, quality of maintenance, and operating hours per year.

Ownership costs and maintenance costs should be approximately equal per year.

Table 3 illustrates typical costs for a 13 m³ (17 cu yd) shovel, and shows averages over a 10-year period, 3-shift, 7 day-per-week operation. Each year will be higher or lower, depending on repairs and replacement parts during the year. The figures represent a hard rock metal mine.

Ownership costs are given in Table 4 for a typical 13 m³ (17 cu yd) shovel operating in the US.

Machine Selection

Shovel selection, like other large dollar expenditures, attracts top management attention and often price and personal preference become the selection criteria. In past years other criteria have been:

1) *Weight*—with today's use of high alloy steels and improved design, weight is often confused with strength.

2) *Horsepower*—rated motor horsepower alone does not take into account the thyristor or generator capacity required to "drive" the motor.

Considerations for correct shovel selection from a technical standpoint will be weight (in certain locations) and

WORKING RANGES (Based on 25 Cubic Yard Mining Dipper)

A — Boom Angle	45°
B — Dumping Height — Maximum	33'-6"
C — Dumping Radius @ Maximum Height	56'-0"
D — Dumping Height @ Maximum Radius	23'-10"
E — Dumping Radius — Maximum	57'-8"
F — Cutting Height — Maximum	52'-0"
G — Cutting Radius @ Maximum Height	60'-6"
H — Cutting Height @ Maximum Radius	28'-8"
J — Cutting Radius — Maximum	67'-6"
K — Radius of Clean-up	46'-10"
L — Clearance Radius — Outside Boom Point Sheave	49'-9"
M — Clearance Height — Over Boom Point Sheave	52'-3"

Fig. 19. Range drawing for a typical 19-m³(25-cu yd) mining shovel.

Table 1. Example of Production Calculation for a 13-m³ 17-(yd³) Shovel

Material weight (in situ) cu yd	4000 lb
Swell factor, 1/1.3 (assume 30% swell)	0.77
Material weight (loose cu yd)	3077 lb
Dipper size	17 cu yd
Fill factor (estimated)	0.85
Cycle time (average, sec)	28
Stph (theoretical)	2858
$\frac{3600}{28} \times 17 \times 0.85 \times \frac{3077}{2000} =$	
Availability, %	83
Stph (practical)	2372
Stph loading trucks (assume 80% truck/shovel efficiency)	1898

Note: This is shovel production only. To calculate mine production, the truck efficiency must also be considered. Metric equivalents: lb \times 0.453 592 4 = kg; st \times 0.907 184 7 = t; cu yd \times 0.764 554 9 = m³.

Table 2. Mining Shovel Productivity, per scheduled hour

Capacity, cu yd	Loading, Rock, bcy	Loading, Rock, st
8	330-460	650-900
12	500-690	1000-1350
17	700-1000	1400-1900
25	1050-1450	2050-2800
32	1300-1850	2600-3600

* Assumes average conditions, loading trucks, minimum swing angle, 0.85 fill factor, and material weight 3000 lb per loose cubic yard. Metric equivalents: cu yd \times 0.764 554 9 = m³; st \times 0.907 184 7 = t.

horsepower, but a better analysis would be to compare performance curves of each motion. Swing torque (ability to accelerate and decelerate from a still position) is important. Swing rpm is not important as the shovel swings are usually 90° or less. Swing is the largest component of cycle time. Hoist effort is important, so as not to stall in the bank, as stalling the motor increases cycle time and contributes to motor burnout.

Crowd effort is least important in terms of cycle time; however, crowd effort and speed must be matched to the hoist effort and speed for ease of operation and maximum production. A general rule often used is that crowd effort should be one-half of hoist effort at stall. Refer to Figs. 20-25 for performance curves of a typical shovel.

Table 3. Example of Operating Costs for a 13-m³ (17-cu yd) Shovel

	Per Hour
Operating labor (operator \$16, oiler \$14)	\$ 30.00
Power (360 kW/h @ \$0.05/kWh)	18.00
Operating supplies (lube, wire, rope, teeth)	15.00
Mechanical maintenance labor	20.00
Mechanical maintenance parts	20.00
Electrical maintenance labor	8.00
Electrical maintenance parts	10.00
Operating cost per hour	\$121.00
Operating cost per ton (assume 1900 stph)	\$ 0.064

Table 4. Example of Ownership Costs for a 13-m³ (17-cu yd) Shovel

Price f.o.b. factory including options	\$3,400,000
Freight, ballast, erection	300,000
Cost of investment	\$3,700,000
Depreciation straight line per year (assume 20-yr life)	\$ 185,000
Taxes, insurance, interest: 20%/yr	\$ 388,500
$\frac{20 + 1}{2 \times 20} \times \$3,700,000 \times 0.20$	
Annual total	\$ 573,500
Assume 6000 hr per year	
Ownership cost per hour	\$ 95.58
Assume 1900 stph	
Ownership cost per ton	0.050

As stated earlier, sizing of the excavator depends on many criteria:

Infrastructure—when the mining company must supply housing, town services, etc., each additional worker together with his dependants and service people contributes to cost per ton or pound of product. In this case, the largest machine may be the best.

Fig. 20. Electrical performance curve for a typical 19-m³ (25-cu yd) mining shovel showing hoist pull vs. hoist line speed.

Fig. 21. Electrical performance curve for a typical 19-m^3 (25-cu yd) mining shovel showing crowd-out effort vs. crowd-out speed.

Fig. 22. Electrical performance for a typical 19-m^3 (25-cu yd) mining shovel showing swing rack torque vs. swing (cab) speed.

Fig. 23. Electrical performance curve for a typical 19-m^3 (25-cu yd) mining shovel showing swing time vs. swing angle.

Fig. 24. A cutting force curve for a typical 19-m^3 (25-cu yd) mining shovel.

Bench height—the shovel teeth should be able to scale the crest of the bank. Safety laws may govern.

Tonnage required—shovel size should be the largest available to produce the tonnage within the constraints of blending, number of ore and waste faces needed, and ore grades available. However, consideration must be given to the mining system as a whole. For instance, one large shovel, when down, will leave the truck fleet idle and the possibility of other phases of the operation, such as crushers, etc., dependent on this situation.

Maintenance facilities—proper crane capacity, shop over-haul facilities, and warehouse stock levels may dictate the size needed.

Truck size—the needed production by the truck fleet along with ore deposit will dictate shovel sizing. Thought should be given to future truck sizes as the haulage fleet may be economic only for ten years, whereas the shovel will be economic for twice that period.

Dipper size—each size shovel is capable of many dipper sizes, depending on dipper and material weights. Once the general size range of shovel is decided upon, discussions with manufacturers should firm up the exact specifications required, dependent upon fragmentation, weights of materials, maintenance systems, union contracts, etc.

Fig. 25. Electrical performance curve for a typical 19-m^3 (25-cu yd) mining shovel showing propel tractive effort vs. propel speed.

HYDRAULIC EXCAVATORS

THOMAS I. FILES

During the 1970s the hydraulic excavator gained rapid acceptance in worldwide surface mining applications. Its acceptance first occurred in the European-influenced markets utilizing the 3.8 to 7.6-m³ (5 to 10-cu yd) capacity machines then available to the mining industry. This size machine, equipped as a face shovel, was used in lieu of the wheel loader or small cable shovel then prevalent in surface mines, dominated by North America's mining techniques.

The early use of the hydraulic excavator, either as a shovel or backhoe, strongly indicated that this machine had some inherent advantages over the front end loader or mining shovel in some mining applications. Key advantages over a front end loader or mining shovel are:

Front End Loader

Lower hydraulic excavator operating costs due to:

- 1) Elimination of tire maintenance cost.
- 2) Less horsepower consumed to load material, therefore, fuel cost per yard of material moved is lower.
- 3) More rugged structural and drive train components may be used, since the front tire and axle loading are not the predominant machine design parameters.
- 4) Greater digging forces (crowd and breakout) may be applied to the material bank.

Mining Shovel

- 1) Greater mobility (if diesel driven), higher travel speed, and more important, weight and improved steerability are available with the hydraulic excavator.
- 2) A digging envelope permitting selectivity in penetrating the bank.
- 3) Higher cutting forces.

With the acceptance of the larger size of hydraulic excavator, there is a demand for hydrostatic components (pumps, motors, valves, cylinders, filters, and hoses) of a higher rated horsepower for larger sizes of machines. As these higher horsepower components are developed, larger sizes of machines are becoming available. Ten makes and models of hydraulic excavators are currently available from European and US manufacturers. For convenience, the makes and models listed in Table 5 are listed by 11.5, 15.3, and 23-m³ (15, 20, and 30-cu yd) shovel buckets.

Unlike front end loaders or mining shovels, hydraulic machines are in a period of dynamic product development. New models offer lower production cost through basic design improvement that increases the machine efficiency and re-

duces maintenance cost. Therefore, an owner may choose to retire or place a machine in a less utilized function and replace it with a more efficient, new model sooner than rebuild cost dictates. (Refer to Fig. 7.)

Hydraulic Excavator Terminology

Confusion can develop in comparing the sizes of front end loaders, mining shovels, and hydraulic excavators, unless the different methods of rating the buckets or dippers of the three products are understood. A dipper rating standard developed by the Power Crane and Shovel Association is generally, but not necessarily, used by cable shovel manufacturers to indicate the size of their products. The bucket rating standards developed by the Society of Automotive Engineers (SAE) is predominantly used by hydraulic excavator manufacturers to note the capacity of their products. When evaluating one type of machine vs. another or when comparing the same type of machine, the manufacturer's rated payload in pounds of capacity should be used as the most accurate indication of capacity.

The SAE has also published a list of standard terminology to be used when discussing hydraulic excavators. For instance, a hydraulic excavator equipped with a shovel front is officially called a *hydraulic shovel* when used in mining.

Machine Description

A general machine description applicable to all makes and sizes is not possible as there is considerable variation within each, although some common features do exist:

- 1) *Hydraulic pumps*: All manufacturers use variable displacement piston types.
- 2) *Hydraulic motors*: Again, piston-type motors are used.
- 3) *Operator controllers*: Joysticks are used for the normal operation function.
- 4) *Swing bearing*: Universally used.
- 5) *Power*: Diesel engines or a-c electric motor driven.
- 6) *Fast field assembly*: Ranging from 50 to 250 man-hr, depending on size.
- 7) *Low ground bearing pressure*: Ranging from 68.9 to 172.4 kPa (10 to 25 psi), depending on size and manufacture.
- 8) Dual path hydrostatic propel drive.
- 9) Dozer-type crawler component through the 11.5 m³ (15 cu yd) class.
- 10) Use of planetary reduction gearing.

Illustrated in Fig. 26 is the common nomenclature features that would be applicable to each major component of a typical hydraulic shovel.

Table 5. Large Hydraulic Excavator Makes and Models

Size Class, cu yd	Make	Model	Capacity, cu yd Shovel	Approximate Working Wt, lb	hp
+15	P&H	1550	15	450,000	1100
	Demag	H 185	15.6	419,000	1000

	Demag	H 485	34	1,200,000	2103

Metric equivalents: cu yd \times 0.764 554 9 = m³; lb \times 0.453 592 4 = kg; hp \times 0.746 = kW.

Fig. 26A. Hydraulic excavator nomenclature.

Fig. 26B. Hydraulic excavator cutaway view, front shovel version.

Maintenance and Estimated Component Life

Hydraulic shovels require maintenance procedures that are unique to this product. Maintenance of the relatively simple hydraulic circuits on haul trucks, dozers, front end loaders, and similar machines does not necessarily qualify the mine's maintenance department to maintain or repair the hydrostatic systems used on hydraulic shovels or backhoes.

The life of the major components used in the power train of hydraulic shovels and backhoes is undergoing rapid improvement by manufacturers in development of systems as well as the individual components. Most manufacturers offer the major components on a rebuild exchange basis to minimize repair cost and downtime.

Replacement time will vary for individual manufacturers, as well as the conditions and maintenance at a specific mine. As a general rule of thumb, replacements should be considered when components reach the following hours:

Component	Operating Hours
Cylinders	3,500- 5,000
Main pumps	5,000- 8,000
Swing motors	4,000- 7,000
Propel motors	12,000-15,000
Valves	Over 15,000
Operator controllers	3,000- 5,000
Diesel engine: Top	6,000- 8,000
Major	10,000-12,000
Clutch	Over 15,000
Torsional dampener	Over 15,000
Hoses	Over 15,000
Propel brakes	Over 15,000
Swing brakes	4,000- 7,000

Application

Comparison of Hydraulic Shovel with Front End Loaders and Mining Shovels: Before developing application studies using hydraulic shovels and hoses, the unique abilities of the machine as compared with front end loaders, mining shovels, or draglines should be considered. The key unique features of the hydraulic shovel are:

- 1) Higher penetrating forces per bucket capacity that may be applied to the bank and that affect bucket fillability.
- 2) Ability to penetrate the bank at any elevation above the pit floor permitting *top down* and selective loading.
- 3) Flat pass capability which is particularly effective in thin seam material loading.
- 4) High mobility when compared with an electric powered mining shovel.

Bucket Factor: The hydraulic shovel bucket may be pivoted at any point within the operating envelope to permit driving the bucket teeth into the material face, allowing removal and loading from the top of the material face downward. This feature, not available on mining shovels, assists in preventing any material overhang that may occur in poorly blasted material. This ability also allows the operator to segregate and load different material in the face.

Truck Sizing: The majority of the hydraulic shovels used in surface mining are equipped with the *clam* type bucket. The clam action bucket allows the machine operator to control the dump speed. Reduced material dumping speed, particularly on the first load, will reduce the shock load on the haul truck bed, chassis, suspension, and tires. This allows the hydraulic shovel to operate with smaller capacity trucks than practical with mining shovels. The dumping target or bed size becomes more of a criterion than maximum bucket load per pass.

Productivity Estimates

The factors that affect the productivity of a hydraulic shovel or backhoe are the same as those used in calculating production for front end loaders, mining shovels, and draglines. Some variation could occur between brands of machines due to differences in bucket crowd and breakout forces, swing speed, and, more important, swing acceleration and braking time. For additional information on productivity estimating, refer to *Productivity* in the Walking Dragline section.

Ownership and Operating Costs (O&O)

Actual ownership costs will probably be unique to each owner and dependent on his individual depreciation rate, interest, taxes, and insurance.

For a comparison of the O&O cost of one type of machine with another (hydraulic shovel vs. mining shovel or front

Table cont.

Line 23: For standard production rate, use 1230 bcy/scheduled hour for front shovel (20 cu yd bucket with 28 sec/cycle) and 920 bcy scheduled hour for backhoe (16 cu yd bucket with 30 sec/cycle) based on 50 min per hour, 80% availability, 90% fill, and 25% swell. Bank height assumed between 3 and 35 ft.

All prices are in US funds.

Prices provided here are budget only. The costs and production rates calculated are for estimation purposes only.

end loader), it is recommended that no residual value be considered at the conclusion of the economical life of the machine. Used machine market conditions at that time may vary from their current scrap value to 25% of the value of a new replacement machine.

Table 6 is a sample work sheet that contains the factors necessary in calculating O&O. Representative estimated production, maintenance, and power cost data is given for a 15.3-m³ (20-cu yd) hydraulic shovel. Table 7 presents an example of a production calculation.

STRIPPING SHOVELS

Stripping shovels, as opposed to mining or quarry type shovels, are normally very large machines with large dippers and long booms and handles. Mining shovels in coal and metal operations are shown in Figs. 27 and 28. They are mounted on four sets of two crawlers, each independent of the other three and able to be hydraulically controlled vertically to conform to the ground contour. At times, large two-crawler shovels are designed with long booms to achieve the same type of stripping, but to a smaller height and reach than the stripping shovel (See Fig. 4).

Stripping shovels evolved from long-range, small dipper configurations in the early 1900s, to the Marion 6360 137.6-m³ (180-cu yd) shovel built in 1966 (see Fig. 2). The eight-crawler design is unique to large stripping shovels. Other features generally associated with stripping shovels are long booms: 30.5 to 67 m (100 to 220 ft); large dippers: 15.3 to

Table 7. Example of Production Calculation for a Hydraulic Shovel

14. St/hr, practical (Item 8 × Item 10 × Item 12)	2565

These calculations are estimates of the hydraulic shovel possible production; to calculate the actual shovel and mine production, both the mine management rating and the truck efficiency must also be considered.

Fig. 27. A typical mining shovel in a coal loading application. BE Model 295-B.

137.6 m³ (20 to 180 cu yd); mammoth weight: 907 185 to 1 224 699 kg (2 to 27 million lb); hinged dipper handle; and propel motors on crawlers.

A deck layout of a stripping shovel is shown in Fig. 29. This shows the multiple motors utilized to provide hoist and swing effort and the multiple motor generator sets utilized to provide power to the d-c motion motors of hoist, crowd, swing, and propel.

All stripping shovels use electric Ward Leonard control of the motion motors. In this system, an individual generator directly connected to the a-c driving motor supplies power electrically to its mating d-c motor.

Use and Application

While there are a few stripping shovels at work outside the US, most of these large machines currently work in the

midwestern US, stripping overburden from seams of coal. Generally, these coal seams are covered by less than 30.5 m (100 ft) of overburden and are reasonably flat lying.

The last stripping shovel was sold in 1969 and the trend is to utilize large walking draglines instead of shovels. The shovel must work in the pit, as opposed to above it and, with the shallower overburden depth seams being exhausted, coal mines must go to equipment able to handle these deeper seams. A rule of thumb commonly used is that the shovel can handle overburden depth roughly one-half the boom length; thus, a 61-m (200-ft) boom is required on a shovel to be able to spoil 30.5 m (100 ft) of overburden.

The mammoth structure of base and crawlers adds more weight to a shovel than a tub and walking mechanism does to a dragline; thus more weight is required per yard of capacity in the shovel. Another item that adds weight is the crowd handle, which is not utilized on a walking dragline.

Fig. 28. A typical mining shovel loading operation in a metal mine. Marion Model 201 m

Fig. 29. Stripping shovel deck layout.

Generally, with regard to spoil reach, the cost per invested dollar is less with a dragline than a shovel.

Shovels do work in tandem with draglines, with the dragline taking the top cut and depositing it far enough away from the lower shovel cut so the shovel has room to spoil the material. Alternately, a smaller *pullback* dragline may be used to take excess spoil which the shovel cannot handle and deposit it in the previous cut, giving the shovel additional spoil area.

A typical spoil diagram for a stripping shovel in a two-seam operation is shown in Fig. 30. The shovel is shown in its pit digging the cut ahead of itself and depositing the spoil material 90° from the cut direction. The shovel sits on top of the coal or other mineral. Slope of the spoil and highwall and depth and width of cut determine the dumping radius of the shovel required. This is for a straight cut. Stripping with either inside or outside curves will allow lesser or greater spoil room for the shovel and give it more reach or radius.

WALKING DRAGLINES

JAMES D. HUMPHREY

The dragline mining system is a relatively simple, versatile, low cost mining method. A single dragline has the capability of operating over a wide range of overburden depths and material characteristics. It is particularly adept

in dealing with overburdens that have fairly low cohesion and/or high water content. In addition, the dragline is quite capable of working very competent rock that has been blasted. Fundamentally, the walking (tub-mounted) dragline (see Fig. 31) differs from other types of draglines, e.g., crawler- or truck-mounted, only by its working base and the means by which it propels.

The walking dragline is slower, hence less mobile, but is more maneuverable and, because the weight is distributed to a tub, it has lower ground-bearing pressures. Because of the capital associated with the larger size of walking draglines, they are generally used in long-life (10 to 40 years) operations.

Walking draglines encompass an extensive range of bucket capacities from approximately 7 to 168 m³ (10 to 220 cu yd); all draglines with bucket capacities above 15 m³ (20 cu yd) typically fall into the walking dragline classification. Boom lengths of walking draglines vary from approximately 37 to 128 m (120 to 420 ft) long.

Crawler-mounted draglines (see Fig. 58) are generally limited to bucket capacities of less than 19 m³ (25 cu yd). The crawler dragline is generally utilized in operations that require more mobility (propel speed). In addition, it is applied in one location for a shorter duration than a tub-mounted dragline. Crawler draglines, due mostly to their size, lend themselves to bolt and pin assemblies and diesel power, both desirable features for short-term operations.

Fig. 30. Stripping shovel two-seam cut sequence.

Fig. 31. 58-m³ (75-cu yd) class dragline, Marion Model 8200.

Machine Features—Mechanical

The mechanical features of a walking dragline can be divided into seven basic components: the tub or base, rotating frame, swing machinery, hoist and drag machinery, propel machinery, the bucket, its ropes and rigging, and the front-end components (see Fig. 32).

Tub: The tub is a rigid circular base that provides complete support for the dragline at all times except during propel mode (see Fig. 33). The weight of the upper components of the dragline transferred to the tub by the roller circle, an independent ring of interconnected rollers that acts as a large bearing for slewing of the rotating frame. The center journal transfers the lateral forces (drag forces) to the tub and provides the transfer point for the electrical power from the trail cable via the collector rings to the electrical equipment on the rotating frame. The rotational forces (during swing) are transferred by main rotating gear segments. These gear segments are bolted to the tub and form a ring gear, which on some machines can be as large as 16.5 m (54 ft) in diameter.

Rotating Frame: The rotating frame or machinery deck is the main platform of the dragline through which the reactive forces of swinging, digging, and propelling are distributed (see Fig. 34A). The rotating frame rests on the roller circle and rotates about the center journal during the swing motion. All machinery and superstructure components are mounted to the rotating frame. (See Fig. 34B).

Swing Machinery: The swing machinery consists of a number of individual swing units mounted to the rotating

frame (see Fig. 35 and 36). Each of these swing units, of which there may be from one to eight, is comprised of a vertically mounted d-c motor which, through a series of gear reductions, drives a main swing shaft. The main swing shafts, to which the swing pinions are attached, extend vertically below the rotating frame and mate with the main rotating gear segments which are mounted to the tub and thereby slewing the rotating frame (see Fig. 35). More recently, the concept of using smaller but more numerous motors (up to 16) and planetary gear cases has been implemented.

Hoist and Drag Machinery: The hoist and drag machinery consists primarily of motors, gear reductions, and wire rope drums. These can be found in two basic arrangements: the independent or the synchronous hoist and drag system. The independent arrangement is utilized on all sizes of walking draglines, while the synchronous arrangement is utilized only in draglines with less than 15 m³ (20 cu yd) of rated bucket capacity.

The independent hoist and drag system is comprised of two sets of separate and independent d-c motors and gear reductions, each of which drives a rope drum (see Fig. 37). As few as one or as many as 12 motors, depending on machine size, may drive either gear reduction. The gear ratios and motor horsepower will generally be the same for the hoist and drag. The placement of the drag drum in front of the hoist drum or vice versa and whether the ropes are overwrapped or underwrapped on the drums varies between manufacturers and/or machine models.

Fig. 32. Exploded view of the 8200 walking dragline showing the basic components.

A synchronous hoist and drag system differs from the independent system because its hoist and drag gear reductions are driven by the same motor (see Fig. 38). The gear reduction units are interconnected and therefore rotate together. The rope drums are clutched to the reduction units, so that the drums may be disengaged either individually or coincidentally, if necessary. An undriven drum, when disengaged from the drive, may be held stationary with an independent brake. These clutching and braking actions are independent of each other and are controlled by the operator. The ropes are normally directed around their respective drums so that when one drum reeves in its rope, the other drum is paying out its rope or vice versa. This is the normal pattern of rope movement during the largest part of a typical digging cycle.

Propel Machinery: Much like the hoist and drag machinery, the propel machinery is commonly found in two configurations: independent and interconnected. On the independently propelled dragline, there are two propel units. Each unit is comprised of one or two d-c motors, a gear reduction, a walking eccentric, and a shoe (see Fig. 39). The propel units are mounted on the sides of the rotating frame (see Figs. 34A and 34B). There is considerable variety in the design of the units, especially the walking eccentric component. However, they all accomplish a similar walking action, which is to move the shoes simultaneously through a nearly elliptical pattern. As the shoes are driven through the lower part of the propel motion, they contact the ground

and begin to take the weight of the machine. The propel units are placed on the rotating frame to the rear of the center of gravity, so as the shoes accept the load, the dragline is tipped a few degrees forward and the rear of the tub is lifted clear of the ground. As the propel motion continues, the propel units slide the machine 1.8 to 2.4 m (6 to 8 ft) to the rear and set it down. The front edge of the tub remains in contact with the ground and will carry about 20% of the weight of machine. The shoes will carry the remaining 80%. The final movement in the propel cycle lifts the shoes clear of the ground into the carry position at the top of the eccentric. The machine is now prepared to take another step or switch to normal swinging and digging operations. Since the propel unit is built into the rotating frame, the dragline may rotate and propel virtually in any direction; the only major restriction is boom clearance.

In some older or smaller models, the propel units are interconnected with a propel shaft driven from a single point. Often the propel drive in this type of system is taken from the drag motors through a jaw clutch. Propel systems that utilize hydraulic power and/or have three or four propel units have been developed for a limited number of special machines.

It is vital that the left and right propel loads occur as nearly simultaneously and equally as possible to minimize stress to the propel components. This requires some method of coordination between the units. On the interconnected type of propel system, the propel shaft provides the timing.

Fig. 33. Diagram of the tub for a walking dragline with roller circle rotating gear and center journal.

In modern independent propel systems, computers control motor loads and eccentric travel differences.

Another common propel system is the crawler frame and mechanism (see Fig 58). This is a common means of locomotion in a mine. The crawlers for draglines are most noticeably different because they are designed for high dead-weight loads rather than for high speeds or tractive effort.

Bucket, Ropes, and Rigging: The purposes of the ropes and rigging are to manipulate the bucket (see Figs. 40 and 40A). The raising and lowering is a function of the hoist rope. The forward and rearward movements are controlled by the drag rope tension. Lateral control is maintained by

the swing motion. The bucket pitch attitude is controlled by the tension in the dump rope which is mainly influenced by the drag rope. However, to varying degrees, the hoist rope may affect attitude depending on the relative position of the bucket to the point sheave.

Front-End Components: The front-end components consist basically of the boom and its support structures (see Fig. 41 and 42). Some smaller draglines may have *live* booms that can be altered to any required angle by the operator. However, since the boom angle has such a pronounced effect on the load-carrying capability of the boom and the rotational inertia of the machine, the angle is usually fixed between 27° and 40° by design. Boom support structures vary greatly between manufacturers and models, but generally take on one of a number of configurations. The gantry (or A-frame) is typically found on smaller model machines (see Fig. 43). When the boom lengths exceed the 60 to 90 m (200 to 300 ft) range, it becomes necessary to alter the front-end geometry of the machine. In order to provide sufficient angle between the main boom support ropes and the boom to meet design load requirements for acceptable boom loading, the machine may be equipped with a mast-gantry (see Fig. 42A) or a tri-structure (see Fig. 42B). In addition to the main support ropes, some larger booms will utilize one or more sets of intermediate boom support ropes to aid in the distribution of boom support loading. Crawler and small walking draglines are similar; because of their size, the front end components are less complicated and live booms tend to be more common.

Machine Features—Electrical

The drive motors on the swing, drag, hoist, and propel, as mentioned previously, are normally d-c motors due to the requirement for variable speeds and for high torque at low speeds. A-c systems have recently been introduced for use in smaller excavators.

D-c voltage is provided by one of three methods: the first, and most common, is an a-c feed to the machine and a Ward Leonard system to convert to d-c voltage. The Ward Leonard system accepts an a-c feed at one of a number of preselected voltages, which in turn is transformed and used to drive an a-c synchronous motor(s). The a-c motor mechanically drives a set of d-c generators that provide the d-c voltage to the drive (hoist, drag, swing, and propel) motors.

The second method of a-c feed utilizes a static power conversion (SPC) system to convert the a-c voltage to d-c voltage. This system eliminates the rotating equipment, a-c

Fig. 39. Walking mechanism.

synchronous motors, and d-c generators (MGs) by the use of solid-state thyristors. The thyristors alter the incoming a-c voltage to d-c voltage. This system is fairly new and is currently offered only on smaller machines.

The third method is the diesel generator system in which the dragline has an on-board or independent skid-mounted diesel generator(s) that provides the necessary a-c voltage to either a Ward Leonard or a SPC system. The diesel generator systems are typically confined to the 15-m³ (20-cu yd) class and smaller machines.

The a-c system, referred to as *a-c variable frequency drive*, utilizes an a-c feed, converts the power to d-c voltage, and

Fig. 38. Drum and motor arrangement (synchronous hoist and drag).

Fig. 40A. Twin dump rope bucket.

Fig. 40. Bucket rigging and ropes.

then back to a-c voltage at a different frequency. Both conversions are done by static power conversion equipment. This final a-c power is used to drive a-c motors. The frequency variation is in response to the operator's controls and allows the use of a-c motors as drive motors. This system has been only recently applied to draglines and is typically confined to the 15-m³ (20-cu yd) class and smaller machines.

Application

In the most common dragline operations, the dragline removes overburden material to uncover an ore (product) in a pit that is the most recent in a series of parallel adjacent pits. These pits are relatively long and narrow. The over-

Fig. 41. Walking dragline nomenclature.

Fig. 42A. Mast and gantry.

Fig. 42B. Tri-structure.

burden material from the current pit is placed in the previous adjacent pit from which the product has been removed by auxiliary equipment (see Fig. 44).

Dragline pits vary greatly in overall length due to the influence of geology, topography, and man-made obstacles. For larger machines, pits in the order of 300 to 3000 m (1,000 to 10,000 ft) long are common. In shorter pits, the sequencing of product removal is difficult and ramp construction becomes more frequent. In longer pits, power dis-

Fig. 43. Gantry (A-Frame) style dragline, Marion Model 7620.

tribution systems become expensive and complex and dragline propel distances can be excessive.

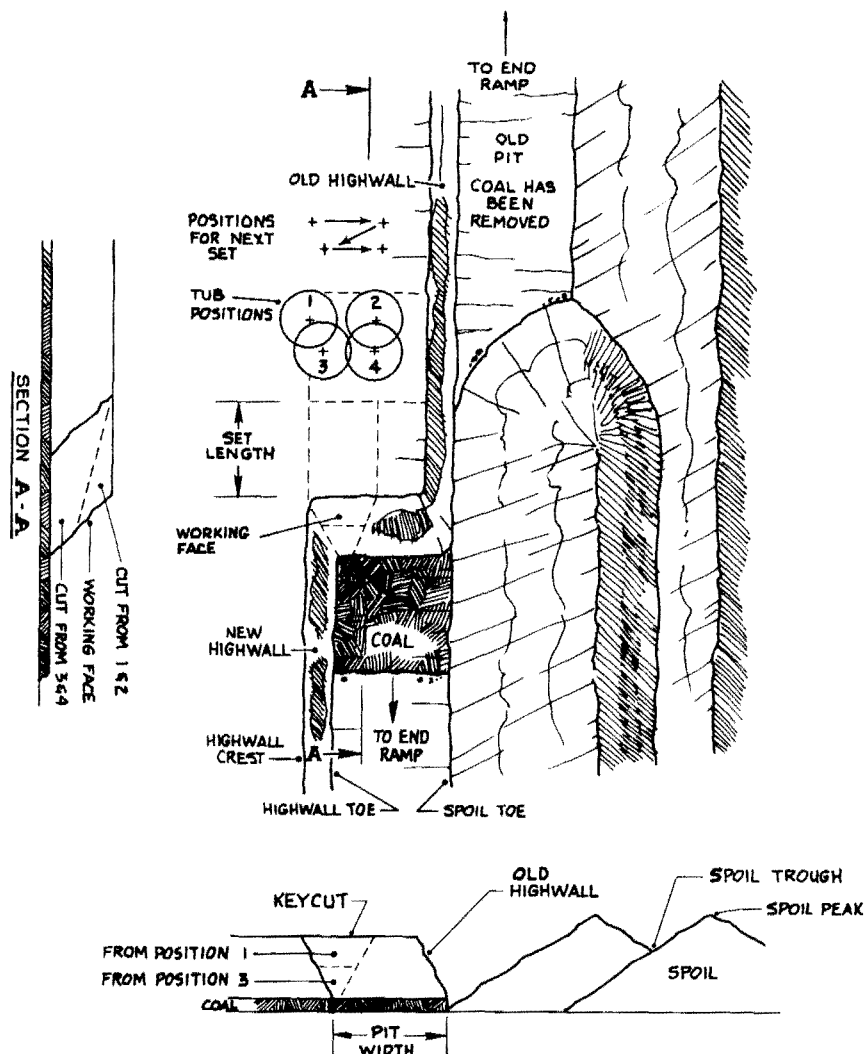

Dragline pit widths commonly vary between 25 to 60 m (80 to 200 ft) variance from either extreme occurs to cope with local conditions and equipment. Pit width is influenced by the maneuverability of product removal equipment, depth of overburden, blasting pattern, material characteristics, dragline advance rate, and dragline dumping radius. In North America, 37 m (120 ft) is a common width in conventional operations.

Box Cuts: In order to initiate this series of parallel adjacent pits, there must obviously be an original pit. This pit is referred to as the *box cut* and has no previous pit available in which to spoil the material. There are a number of methods used to develop the box cut which vary depending on field conditions. Fig. 45 is a typical method.

Operating Methods: The standard dragline application is the *simple side casting* technique in which the dragline removes overburden from a specified length of the pit, referred to as a *set*, swings approximately 90°, and casts into an empty pit. Set lengths for larger machines are in the order of 30 m (100 ft) or about 16 steps for the dragline. To remove the overburden from a set, a dragline may use from two to four tub positions before retreating to start a new set. When the dragline removes the final set at the end of the pit, it may reverse direction and start a new pit. However, the dragline requires the product to be removed from the completed pit before starting the new pit to prevent burying product with spoil. Ideally, the product is being removed in conjunction with the dragline operation, and a constant interval is maintained between the dragline working face and the product face. The dragline must either wait until product material has been removed to provide a place to spoil or it must propel to a location where there is space for spoiling. This time may be utilized as maintenance time or the dragline may perform an auxiliary operation that can be spoiled outside of the working pit, e.g., ramp development. If the wait time is excessive, the dragline may propel to the opposite end of the pit where the product has been removed and initiate a new pit in the same direction as the previous one.

Long propel movements between working faces are referred to as *deadheads*. There are a number of variations in *deadheading* methods to best utilize machine time. Operations commonly operate from end to end as already described. Operating from the ends toward the middle (or vice versa) or to have two pits in close proximity are also common. This will depend on such factors as haulage ramp locations, product pit inventory requirements, terrain and geologic conditions, etc.

Fig. 44. Dragline working area plan section and elevation.

Digging Positions: In fairly consolidated overburden, the four position set (see Fig. 44) is commonly used. The dragline progresses through the positions in numerical order. The first two rear positions are set back far enough to ensure that no material would be too close to the fairlead to be reached. In shallow digging, the first two positions may suffice to reach the product surface. In deeper pits, the digging may soon reach the point where the drag ropes are scouring through the shoulder of the digging face; consequently, the two forward positions are needed to clear the ropes. In the first two (rear) positions, the upper lift of the set is removed. In the last two positions, the machine has moved forward to the edge of the digging face to reach down for the lower lift of the set. The split between these lifts may be equal but usually varies to accommodate geological conditions.

Position 1 fixes the alignment and slope of the new highwall by a *key cut* along the full length of the set. This trenchlike cut, confined to a bottom width of only a single bucket as it works down, allows maximum lateral control of the bucket with a minimum of lateral strain on the boom. When the bottom of the first lift of the key has been reached (generally when the drag ropes begin to touch the crest of the working face), the machine moves laterally into position 2. This *plug or block* position allows the dragline to spoil at

maximum range. As the excavation progresses, the plug is removed in lifts. These lifts are comprised of a series of cuts to an equal depth (about one-half the bucket height) made in a sweeping pattern. The sweeps normally progress from the spoil side to the key so as to minimize any hoisting required before swinging the bucket to the spoil. This done, the machine moves into position 3 and 4 and excavates the lower lift in much the same fashion.

In working with a highwall that has a very low angle of repose, the position 3 key cut block is closer to the spoil than was the position 1 block. In the extreme of this situation, position 3 may move so much closer to the spoil as to overlap position 4. This situation then creates one type of three position set. The positions closest to the spoil (2 and 4) are positioned as close to the highwall as possible to make maximum use of the dump radius. Position 2 also removes the top of the plug so as to reduce the bucket clearance height that the second key position (position 3) must have before swinging.

This description, while typical, should be considered general. Set lengths and digging positions will vary, depending upon operating conditions and utilization of machine capabilities.

The side cast technique is commonly employed in op-

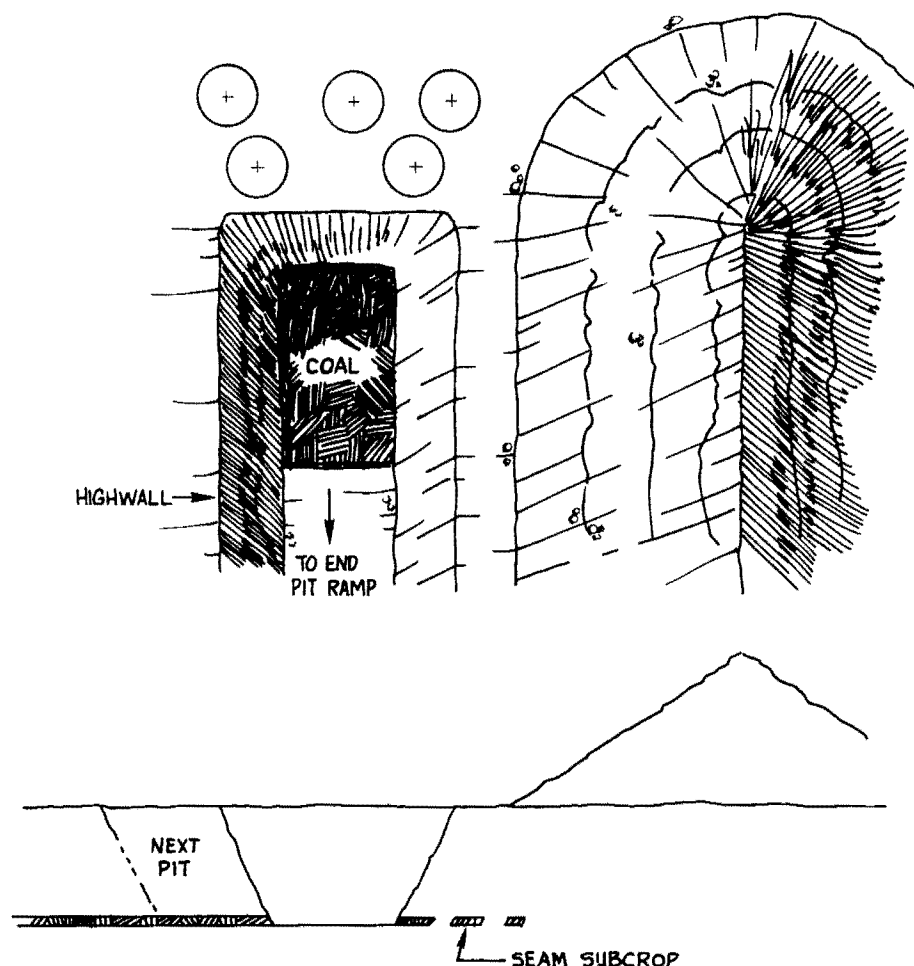

Fig. 45. Box cut.

erations that only want to uncover the mineral or product. Some operations, however, also want to load out the product with the same dragline. This is typically observed in phosphate operations in the southeastern United States. These operations remove the product (called matrix) from the pit with an identical digging method, but dump it into sumps or hoppers on the highwall where it is transported to a processing plant. These operations may not use key cuts because both the highwall depth and angle can be so low that they may only use a two position set (positions 2 and 4); nor do they need to keep the spoil out of the active pit since the matrix is constantly removed. This leads to some very small swing angles and low dump heights, which result in *pay drag dependent* cycles. This is something that does not often happen during normal side casting operations. Similar applications include operations that dump the product on the highwall to be reclaimed by other equipment, or smaller draglines loading directly into trucks or conveyor hoppers.

Digging Cycle: The digging cycle of a dragline is comprised of five components: (1) drag to fill, (2) hoist and swing, (3) dump, (4) return swing, and (5) positioning. The time required for each of these functions will vary depending on a number of factors: slope of the digging face, material characteristics, bank preparation, digging depth, hoisting height, swing angle, rope and swing speeds, as well as operator proficiency. Because of the diversity of these influences, even machines of the same model and design will have

different cycle times. Typical designed cycle time for larger machines is within the range of 50 to 60 sec for a 90° swing with a low dump. Smaller draglines are, as a rule, generally faster than larger draglines.

The dragline cycle begins with the bucket lowered in the pit and positioned to penetrate the bank. Dragging it into the digging face fills the bucket. Although buckets are designed for the teeth to have a good angle of attack in the relaxed position, sensitive handling of the hoist tension at this time can improve the penetration rate and reduce bucket fill time. In a good situation, the bucket will fill to overflowing in two to three times its length. Once filled, hoisting and drag pay out commence almost simultaneously, followed immediately by swinging as the bucket clears the trench. As the bucket swings and climbs, proper tension between hoist and drag holds the bucket in the carry position. As the dumping point is approached, the swing control is reversed (plugged) and the drag allowed to pay out until the bucket is unbalanced and the load dumps. Due to the swing inertia of the machine, the direction of swing will not change for several seconds after the controls are reversed, giving the bucket time to dump without delay. During the return swing, the hoist is payed out and the drag is reeved in so as to begin the positioning of the bucket for the next bite. The swing control is reversed to stop the swing motion, then neutralized as the bucket settles into position. The proficiency with which these five functions are carried out contributes significantly to the productivity of the machine.

Spoiling Techniques: The second component of the cycle is actually three independent movements: swinging, hoisting, and paying out drag. Each of these has a specific time requirement. For almost any particular dump point, one of these movements will take more time than the others. Therefore, two movements are retarded intentionally so that the slower, or *dependent*, movement will have time to coincide at the dump point. If, for example, a particular cycle were a long swing, short hoist, and short pay drag, then the cycle is considered to be a *swing dependent* cycle.

There is a point in space, a specific swing angle from, height above, and distance out from every loaded bucket pickup point, referred to as the coincidental point. This is the point at which the swing, hoist, and pay drag times are equal and as short as possible when the bucket dumps. The location of this point, referenced to the center journal of the machine, varies between machines because rope speeds and swing speeds are very individual. The coincidental point will also move with the location of the bucket pickup point and

any changes made in bucket rigging that would change the dump envelope. Because the pay drag speeds are comparatively fast, the coincidental point is generally at a fairly small swing angle and low dump height, not a very commonly required dump point. If the drag pay were retarded, however, the bucket would follow a curve which is referred to as the *swing and hoist coincidental curve*.

This curve would have an origin near the coincidental point and would terminate when the bucket reached maximum dump height. The bucket then could be dumped anywhere along this curve for the operator to make maximum use of the swing and hoist speeds. Any cycle in which the dump is above this curve would be *hoist dependent*. Any cycle in which the dump is below the curve or at a larger swing angle than the termination point would be *swing dependent*. With this in mind, it becomes obvious that a dragline operator will not just dump on the peak of the spoil every cycle. The operator will attempt to select a dump point as near the swing and hoist coincidental curve as possible. While

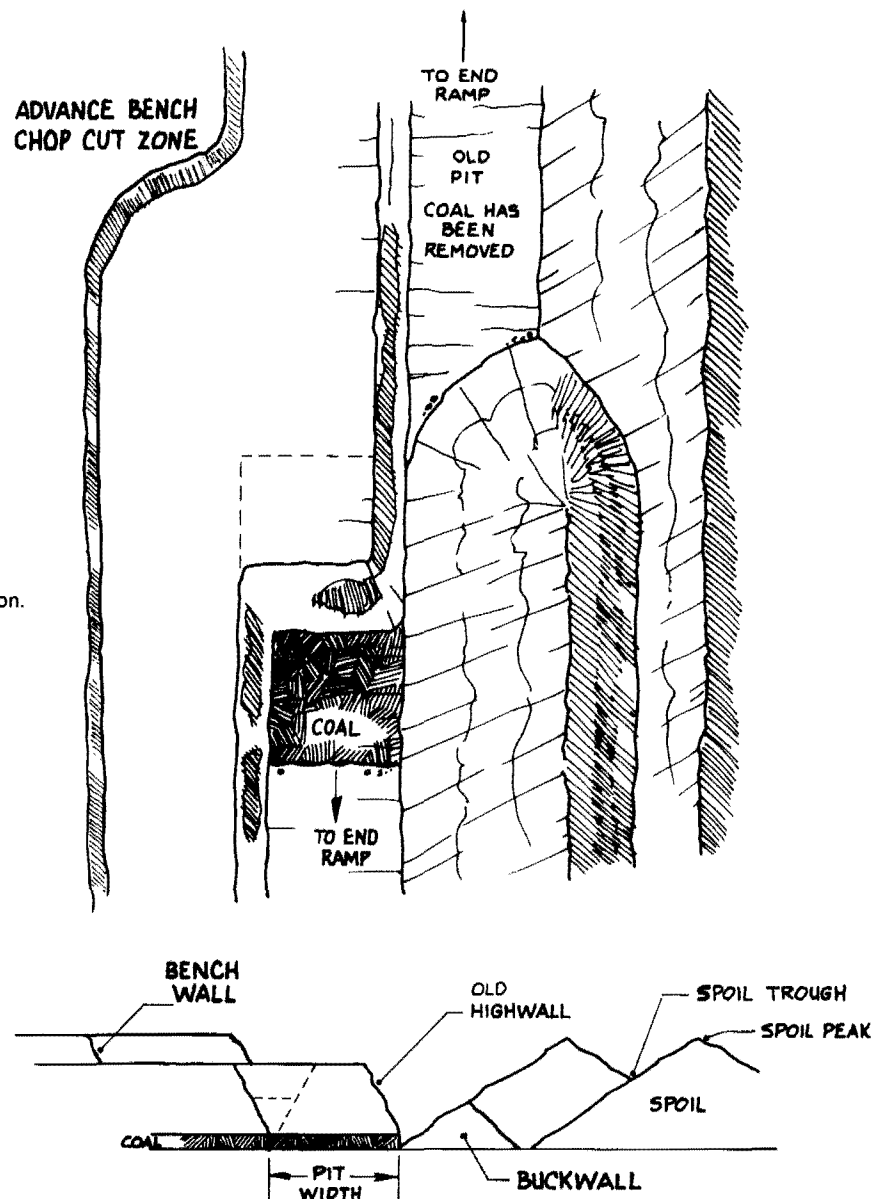

Fig. 46. Advance bench plan and section.

this is not practical for every cycle, the more coincidental cycles that occur the more efficient the operation will be.

Special Operating Techniques: One of the reasons the dragline is such a versatile tool is that it can be applied in a variety of manners. One common method is the *advance bench* (see Fig. 46). This method is very useful in areas with uneven terrain or in overburdens with a top layer of unconsolidated material. Here the set is split into an upper and lower bench. The lower bench is removed conventionally. The upper bench, however, requires a somewhat different technique called *chop cutting*. This is the technique that must be applied when a dragline excavates above its working level. Specifically, the bucket is pulled down a face rather than up or across it. The bucket is usually held in a dump position, teeth down, lowered on to the face, and dragged forward. Operating in a chop-down mode is hard on the rigging, ropes, and bucket, which leads to increased downtime, repair costs, and decreased productivity. Productivity is further decreased by the lower fill factor and increased drag to fill time that result. Advance benching generally requires a longer swing angle as well. The resulting efficiency varies; however, a minimum of 80 to 90% of a conventional rate should be used for initial estimates. It is most effective in unconsolidated overburdens with an advance bench height of no more than the fairlead height. There are operations that utilize a chop down in consolidated materials with bench heights considerably higher than the fairleads. *Chop cutting* is sometimes employed below the working level. Spoil side operations may use it to clean the highwall, rather than using a key cut.

If the material in the advance bench is extremely unconsolidated, it is sometimes convenient to utilize a *buckwall* (see Fig. 46) made of competent material removed from another area of the set. This dry competent material is placed at the toe of the spoil, thus forming a retaining wall. Unconsolidated material from the advance bench chop cut is then placed and contained behind it. This buckwall will add considerable stability to the spoil.

When a dragline does not have enough dump radius to place the spoil far enough away, it may be necessary to utilize one of a number of different spoiling techniques. This requirement for extra dump radius can occur on a localized basis around spoil side ramps, spoil or highwall slumps, high spots in the overburden, or inside curves. It may be required on an extended basis in operations that utilize a dragline with an inadequate dump radius for the overburden conditions. This may be because of limited machine selection at purchase time, capital cost savings for a smaller machine, relatively short period in deep overburden (e.g., 2 years of a 20-year mine life), etc. The advanced bench reduces the required dump radius by the horizontal component of the slope of the bench wall; a small amount, admittedly, but at times adequate. The most common technique utilized in reach limited situations is the *extended bench* (see Fig. 47). In this technique, the dragline places the driest, most competent material from the set against the old highwall. Enough material is placed there that, when leveled, a bench is formed that the dragline will move onto, so as to position itself nearer the spoil. As the excavating progresses, the extended bench is removed; unfortunately some material will have to be rehandled. Although efforts should always be made to avoid rehandling of any kind, in this situation it becomes a necessary function.

In two-seam operations, the placement of the spoil and the sequencing of equipment become more complex. Three methods are common, but not exclusive, in two-seam op-

erations: (1) the two-bench, (2) the pullback, and (3) the extended lower bench. All three methods will move identical overburden combinations; however, they require different sizes of draglines and involve varied amounts of rehandle. The selection of the best method will depend on the relative costs and its feasibility in various scenarios. These three methods could also be applied to single-seam operations in deep overburden.

The most straightforward method is the two-bench method (see Fig. 48). In this method, the upper burden is removed first and spoiled into the bottom of the previous pit and the exposed upper coal removed. The lower burden is removed by simple side cast and spoiled on top of the first spoil. This can be accomplished with one dragline making two passes down the pit or two different draglines working in tandem.

The method has a few difficult points, primarily that the upper burden highwall must be setback (see Fig. 48, unit W_b) enough to provide swing clearance for the rear of the dragline on the lower bench during the key cut. Without this extra space, auxiliary equipment (dozers) must be used to make the key cut. Even though the use of dozers in the key is not uncommon, some operators consider working this close to the highwall unsafe in their conditions. A *setback* increases the required radius for the upper dragline. Also, the dragline on the lower bench needs more height, so any single machine in this application will probably be mismatched for one of the benches.

To help equalize the dragline size requirements, a spoil bench pullback method could be considered (see Fig. 49). This method removes the upper burden in the same manner; however, the spoil from this burden is then leveled and the second pass is made with the dragline on the spoil bench. Operations on the spoil bench may show productivities of 75 to 85% of conventional operations.

Another method would be to use an extended bench for the lower burden (see Fig. 50). In this method, some or all of the material from the upper burden is placed against the lower burden highwall forming the extended bench.

Productivity

Dragline productivity is based upon two primary factors: (1) the number of digging cycles occurring in a given period of time; and (2) the number of bank cubic yards in each bucket. Influencing each of these are several secondary factors, that all combine to govern the productivity rate of a machine. Contributing to the number of buckets are such things as scheduled time, availability, utilization, and cycle time. The yards per bucket are influenced by bucket design, bank preparation, swell factor, and operator skill. Each of these in turn also has its tertiary factors that are part of the foundation of good productivity.

To fully understand how to assess or forecast dragline productivity, clear definitions of some of the more ambiguous variables must be established. In particular, hours and yardage each have distinct categorical variations critical to dragline calculations (see Fig. 51).

1. *Calendar Hours (H_c):* This is the actual total hours in a given period of observation or prediction.

2. *Scheduled Hours (H_s):* This is the time during which the machine is expected to operate. This is the time that remains when hours for scheduled and uncontrollable delays (H_{ds}) are deducted from calendar hours. Scheduled delays are such periods as holidays, vacation, and nonscheduled shifts. Uncontrollable delays are such periods as strike time, adverse weather, power source outage, and other periods

Fig. 47. Simple extended bench plan section.

during which the machine or crews, either operating or support, are given no opportunity to perform. Large dragline operations are typically scheduled to operate around the clock all year long or seldom less than 8000 hr per year.

3. *Available Hours (HA)*: This is that part of the scheduled hours (*HS*) the machine is mechanically and electrically ready to be operated. This is the time that remains when hours for mechanical and electrical delays (*HDM*) are deducted from scheduled hours. These are any delays due to mechanical or electrical problems or repairs, $HS - HDM = HA$.

4. *Utilized or Operating Hours (HU)*: This is that part of the available hours (*HA*) during which the dragline is actually operating at full potential. This is the time that remains when hours for operational delays (*HDU*) are deducted from available hours. These are any delays for losses of digging time such as moving cable or propelling and delays directly due to operational problems, e.g., supervision, labor, and support, $HA - HDU = HU$ or $HS - HDM - HDU = HU$.

There are basically two types of cubic yards: the *bank*

cubic yard (BCY) and the *loose cubic yard (LCY)*. Material, when referred to as being in a bank state, regardless of whether or not it actually is, is considered to have a density equal to that of similar undisturbed (in situ) material. Material once excavated becomes loose and its density is decreased and volume increased. This is considered a material characteristic and varies with fragmentation, water content, etc.

The *swell factor (Fs)* is the ratio of these densities or, more generally, a ratio of volumes of equal weight, as in $LCY/BCY = Fs$; this is sometimes expressed as the inverse of this ratio. As expressed here, *Fs* for most overburdens varies from 1.1 to 1.6. In dragline operations, the material will undergo a number of swell changes. There is swell after blasting, swell in the bucket, and swell in the spoil. For the most part, swell in a dragline bucket is considered to be the same as swell in the spoil or about 1.2 to 1.4.

Productivity of a dragline is based on two primary factors: (1) the actual number of cycles that occur in a given time; and (2) the actual volume in BCY moved every cycle.

Fig. 48. Two-seam two-bench method.

Fig. 50. Two-seam extended bench method.

The number of cycles per year is affected by four parameters:

1. *Observed Cycle Time (TC)*: The time required for the dragline to complete one entire cycle usually expressed in seconds.

2. *Scheduled Hours (Hs)*: As previously defined.

3. *Availability (A)*: This parameter reflects the decrease in scheduled time due to mechanical and electrical delays. A delay for a mechanical or electrical problem is scheduled time that the machine cannot operate because of a mechanical or electrical failure or repair; this includes wear part replacement, welding, etc., as well as major repair work. It does not, however, include delay time for mismanaged transportation of parts or repair labor. Availability varies with the age of the machine, the difficulty of the working conditions, the effectiveness of preventive maintenance the machine receives, the number of hours scheduled, etc. This availability percentage is not only critical to performance predictions but serves also as an indication of the efficiency of the maintenance program. The inclusion or exclusion of preventive maintenance as down hours varies between operators. Operations that exclude it will report higher availabilities. When attempting to correlate availability data, care must be taken to understand the calculating method.

If field data is obtainable, the availability may be calculated by dividing the hours available by the hours scheduled: $(HA)/(Hs)$ or $(Hs - HDM)/(Hs) = (A)$. Conversely, (A) may be estimated and multiplied by the scheduled hours to find available hours: $(A) \times (Hs) = HA$. Availability will vary from 0.95 to 0.70; 0.85 is considered typical.

Fig. 49. Two-seam spoil bench pullback method.

4. *Utilization (U)*: This factor reflects the amount of available time the machine is operated. A delay for an operational problem is available time lost that the machine is not operating because it is waiting on support, e.g., dozer work, cable handling, blasting delays, etc., or performing a nonproductive function, e.g., scaling down the highwall, propping, preparing pad, or just generally being operated inefficiently. Note that utilization is calculated as a percentage of available hours, not scheduled hours. Utilization varies with the competency of the mine personnel, the efficiency of the mine plan, support equipment commitments, etc. This utilization percentage is used in performance predictions and is also an indication of machine management efficiency. If field data are obtainable, the utilization may be calculated by dividing the hours utilized by the hours available: $(Hu)/(HA)$ or $(Hs - HDM - HDU)/(Hs - HDM) = (U)$. Conversely, (U) may be estimated and multiplied by the available hours to find utilized hours: $(U) \times (HA) = Hu$ or $(U) \times (A) \times (Hs) = Hu$. Utilization will vary from approximately 0.95 to 0.70; 0.85 is considered typical. *Note*: Both A and U may be combined into an *operating efficiency* (see Table 8).

The BCY moved every cycle is affected by three parameters:

1. *Rated Bucket Capacity (BC)*: Normally expressed in cubic yards; the units, however, are more accurately expressed as *loose cubic yards rated per cycle (LCYR/cycle)*. This capacity is defined by SAE standard J67.

2. *Swell Factor (Fs)*: As previously defined, expressed as *loose cubic yards per bank cubic yard (LCY/BCY)*.

3. *Fill Factor (Ff)*: This is the percentage of the bucket that actually fills with material, expressed as *loose cubic yards actual per loose cubic yard rated (LCY/LCYR)*. Average fill factors normally vary from 0.80 to 1.00.

Fill factor and swell factor are often combined into a *bucket factor (BCY/LCYR)*. Bucket factor is more practical to calculate from field data than swell and fill. It is surveyed yards (including rehandle) divided by the bucket (or cycle) count.

An estimate of dragline production can now be calculated that is sensitive to adjustments in these seven basic parameters. Not all mining operations will define these basic parameters in this same manner; some operations will use fewer and some more parameters. The equation that follows, however, applies the fundamentals in a straightforward reproducible manner that provides a basis for comparing machines and application methods.

$$(3600/TC) \times (Hs/Year) \times A \times U \times (Bc/Fs) \times Ff$$

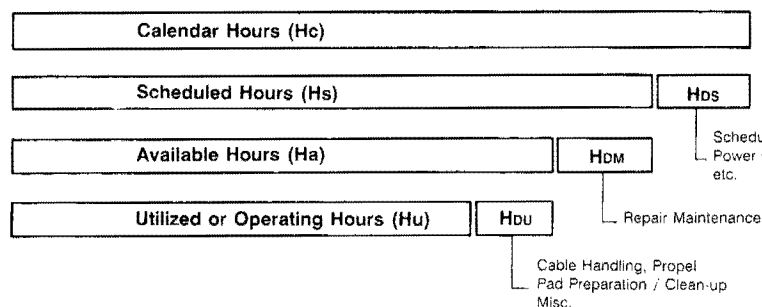

Fig. 51. Hour definition for draglines.

Example:

3600 = seconds/utilized hour
 T_c = 57 seconds/cycle
 H_s = 8000 scheduled hours
 A = 0.85 available hours/scheduled hour
 U = 0.85 utilized hours/available hour
 F_s = 1.3 LCY/BCY
 F_f = 0.9 LCY/LCYr
 B_c = 1 LCYr/cycle

The resulting production rate is approximately 250,000 BCY/year.

Since a one cubic yard bucket was applied, it can be said the production rate is 250,000 BCY/year per cubic yard of bucket. More appropriately, this *production factor* would be 250,000 (BCY/year) per (LCYr/cycle), and when multiplied by the rated bucket capacity per cycle (LCYr/cycle) will provide production rate per year. This, however, assumes that all the other parameters remain constant for all bucket sizes which is seldom true. Although for first round ball park estimating, this factor will prove easy and adequate. For any one mining method in a particular material at the same mine, the only parameters that will usually change between two different draglines are the cycle time and the rated bucket capacity. The production factor would remain the same in metric units, if a 1 m³ bucket were used, the resulting factor would be 250,000 (BCM/year) per (LCMr/cycle).

There is a common misconception that the dragline with the largest bucket is the largest producer; this is only true, of course, if all the other parameters remain constant. The dragline with the smaller bucket will, in fact, most likely have a faster cycle time because it may have less rotational inertia (it swings less load); in such an instance it will swing faster. If the dragline has a longer radius, less swing angle is required to achieve the same reach. This could also result in a faster swing time. Therefore, a 46-m³ (60-cu yd) dragline that cycles in 57 sec will actually produce less than a 45-m³ (59-cu yd) dragline that cycles in 55 sec.

The production factor may also be calculated from actual field production data by dividing the actual yearly production

by the rated bucket capacity. Operating mines will demonstrate production factors from 200,000 to 300,000 (BCY/year)/(LCYr/cycle) quite commonly and values outside of this range do occur. The productivity factor also provides a means for measuring on an hourly basis efficiency of a mining method.

A caution should be pointed out here that some operations report production in *prime*, (also called *virgin* or *in situ*) BCY year labeled as just BCY/year. This is particularly true in countries other than the United States. *Prime* volume is the actual volume of overburden above the coal that was uncovered and does not include rehandle. When in fact most mines experience a minimum of 5 to 10% additional operational rehandle for ramps, bench fill, etc. Operations that utilize an extended bench or other rehandle methods will show even higher rehandle percentages. The production factor calculated using *prime* BCY will be smaller. *Prime* is adequate for comparing machines using the same mining method at the same mine; however, it is not a true measure of the productivity of the dragline. In situations where clarity is required, the use of the terminology *total* (including rehandle) bank cubic yards (TBCY) and *prime* (not including rehandle) bank cubic yards (PBCY) is advisable.

Ownership and Operating Costs

When selecting a dragline, the owning and operating costs are always the bottom line. These costs are generally computed, for comparison purposes, on the basis of either cost per hour (usually scheduled hours), per BCY, or per ton of product. It is easiest, however, to compute the cost per year and divide it by the required base unit. Table 9 is an estimated ownership and operating cost for a typical 46-m³ (60-cu yd) dragline followed by a line-by-line explanation of the required computations. The ownership cost here is calculated by a simple method. A true ownership method would take into account the discounted cash flow over the payment schedule (draglines are not sold or paid for in a lump sum, but instead, over a period of months) and any tax credits that apply. This type of analysis would be too individualized and detailed to be of value here; the analysis method that is used, however, is adequate for preliminary comparison purposes.

Table 8. Operating Efficiency

Availability	Utilization			
	Excellent	Good	Fair	Poor
Excellent	0.84	0.81	0.76	0.70
Good	0.78	0.76	0.71	0.64
Fair	0.72	0.69	0.65	0.60
Poor	0.63	0.61	0.57	0.52

Table 9. 46-m³ (60-cu yd) Dragline—Ownership and Operating Costs Example

Ownership	
1. Purchase price	US \$16,330,000
2. Options and extras	817,000
3. Freight	226,000
4. Trail cable	50,000
a. Subtotal	\$17,423,000
5. Ballast	90,000
6. Erection	2,958,800
7. Total price	US \$20,471,800
8. Depreciation life 20 years	
9. Depreciation cost per year	US \$ 1,023,600
(Line 7)	
(Line 8)	
10. Average investment per year	10,747,700
(Line 7) × (Line 8 + 1 year)	
2 × (line 8)	
11. Interest, taxes, and insurance per year	1,934,600
ITI% × (Line 10)	
12. Total ownership costs per year	\$ 2,958,200
(Line 9) + (Line 11)	
Operating	
13. Maintenance and supply cost per year	US \$1,219,600
7% × (Line 4a)	
14. Electric power cost per year	882,000
15. Labor costs	256,000
16. Total operating costs per year	US \$ 2,357,600
17. Total ownership and operating cost per year	US \$ 5,315,800
Total	
18. Ownership and operating cost/scheduled hour @ 8000 hr/year	US \$ 664
19. Ownership and operating cost/BCY @ 15.0 × 10 ⁶ BCY/year	US \$ 0.354

Line 1: Purchase price is normally f.o.b. factory; see manufacturer for estimate.

Line 2: 3 to 7% of line 1 is a good average; this will include one extra bucket and a standard selection of options.

Line 3: Varies with location, estimate here is for a 1600-km (1000-mile) ship distance at \$60/ton. See manufacturer for specific shipping weights and freight estimates.

Line 4: This cost is estimated for 450 to 600 m (1500 to 2000 ft) of 350 MCM cable at about \$30 per 0.3 m (ft). Conductor size varies with machine and length varies with pit plan.

Line 5: Cost estimated at \$210/ton delivered for steel punchings. See manufacturer for specific requirement.

Line 6: Based on approximately \$37/man-hour, the man-hours required are best received from manufacturer, however, 26 to 30 man-hr per ton of ship weight is a rough estimate.

Line 11: Estimated interest 14% + taxes 2.5% + insurance 1.5%, so total ITI is 18%. This will vary between locations.

Line 13: Includes costs for ropes, wear parts, lubricants, major parts, etc., as well as repair labor, (labor comprises 20 to 45% of costs). The 7% multiplier is based on actual experienced costs. It is, however, averaged for the life of the machine. Some years will have costs significantly above this percentage and some significantly below. For crawler-mounted diesel draglines, this maintenance factor is more in the order of 10%.

Line 14: This cost is based on 14.7 × 10⁶ kWh/yr at \$0.06/kWh. Total power consumption is best obtained from manufacturer; however, consumption varies from 0.75 kWh/(BCY/yr) to 1.35 kWh/(BCY/yr) for small to large machines, respectively. For diesel machines, fuel consumption per hour is usually readily available from dragline or engine manufacturers. Be sure to understand whether the consumption is reported in operating hours or scheduled hours before converting to a per year cost.

Line 15: Includes wages and benefits for operator and oiler for every scheduled hour (8000 hr/year here).

Line 19: Production based on 250,000 (BCY/yr) (cu yd of bucket) total ownership and operating cost should be between \$0.25 and \$0.40/BCY for normal operations.

Dragline Selection

An important concept to keep in mind when sizing or selecting a dragline is to select the dragline for the mine plan, not the mine plan for the dragline. The two major parameters used to select the right dragline are, fundamentally, dump radius and allowable load. Under certain operating conditions other parameters, such as ground bearing pressure of the tub, the rear end swing clearance, dump height, etc., may also affect selection.

1. **Dump Radius (*Rd*):** This is the horizontal distance from the machine's center of rotation to the hoist rope when the bucket is in a vertically suspended position. Part of this dump radius is consumed by *stand-off* (*So*). This is the distance from the center of rotation to the crest of the old highwall when the machine is in a digging position. The remaining dump radius is considered the *effective radius* (*Re*); thus, $Rd - So = Re$. The stand-off distance will vary depending on machine size, operator preference, and overburden conditions. Lacking field data, a minimum stand-off distance of 50% of the width of the dragline from the outside of the shoes, or 75% of the tub diameter, are commonly used values for planning purposes.

2. **Allowable Load:** Sometimes called maximum suspended load, this is the maximum weight of bucket, rigging, and material for which the dragline is designed to provide optimum performance. Standard duty buckets, including rigging, weigh about 2000 lb per rated cubic yard of capacity, though they may vary from 1800 to 2300 lb/LCYr, depending upon the specific application. Some special purpose buckets for small draglines are as light as 1500 lb per rated cubic yard. Overburden weights are site specific; however, 3000 lb/LCY is a commonly used approximation. The combined weight then of a standard bucket and material load would be approximately 5000 lb per rated cubic yard. Therefore, an operation that requires a dragline with a 50-cu yd bucket actually requires a dragline with about a 250,000-lb allowable load. Allowable load should be selected for the 100% full bucket (peak bucket load) even though the average fill is less, e.g., 90%.

Calculating Radius Requirements: The effective radius (*Re*) required to place a spoil pile far enough away so that the spoil remains entirely in the previous pit is purely a function of the material. It is calculated by realizing that the cross-section area of the cut when swelled equals the cross-section area of the spoil; this method requires that the pits be of equal length. Knowing, then, the areas of both sides, the pit width(s), and the angles of repose, it is a minor problem in trigonometry to calculate standardized equations for a number of mining scenarios (see Figs. 52-57).

The effective radius (*Re*) of a dragline is the true indicator of its digging depth capacity; it is not boom length and not even dump radius. Although, for example, two draglines may have the same dump radius, if one were a smaller, lighter machine, it would most likely require less stand-off and therefore have a greater effective radius. Hence, the smaller dragline in the same overburden will be able to dig to a greater depth because it can actually place spoil farther from the crest of the highwall than can the larger machine.

Calculating Rated Bucket Requirements: It is not the objective here to explain how to calculate overburden removal requirements, so it will be assumed that the actual BCY/year requirement is known for each mining scenario selected. In addition it will be assumed that this number has already been corrected for coal losses in the pit and plant and for the overburden rehandle expected for the particular mining scenario.

$$Re = \frac{H_o}{\tan \phi_o} + \frac{H_c}{\tan \phi_c} + \frac{W_{o2} H_o F_s}{W_{o1} \tan \theta} + \frac{W_{o1}}{4}$$

$$H_o = \frac{(Re - \frac{W_{o1}}{4} - \frac{H_c}{\tan \phi_c})}{(\frac{1}{\tan \phi_o} + \frac{W_{o2} F_s}{W_{o1} \tan \theta})}$$

Fig. 52. Simple side cast range diagram and equation.

$$Re = \frac{H_o}{\tan \phi_o} + \frac{H_c}{\tan \phi_c} + \frac{(W_{o2} H_o + W_{o3} H_{AB}) F_s}{W_{o1} \tan \theta} + \frac{W_{o1}}{4}$$

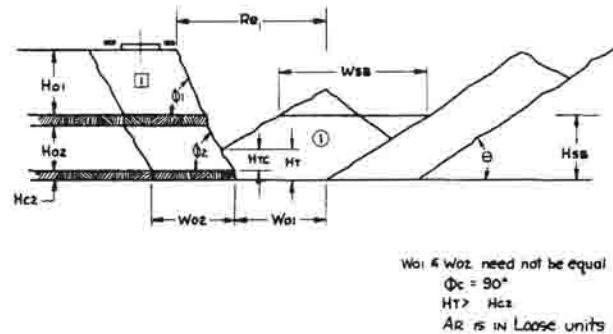

Fig. 53. Advance bench range diagram and equation.

$$Re1 = \frac{H_{o1}}{\tan \phi_{o1}} + \frac{H_{c1}}{\tan \phi_c} + W_B + \frac{H_{o2}}{\tan \phi_{o2}} + \frac{H_{c2}}{\tan \phi_c} + \frac{W_{o2} H_{o1} F_s}{W_{o1} \tan \theta} + \frac{W_{o1}}{4}$$

$$Re2 = \frac{H_{o2}}{\tan \phi_{o2}} + \frac{H_{c2}}{\tan \phi_c} + \frac{W_{o2} (H_{o1} + H_{o2}) F_s}{W_{o1} \tan \theta} + \frac{W_{o1}}{4}$$

Fig. 54. Two-seam two-bench range diagram and equation.

$$Re = \frac{H_{o1}}{\tan \phi_1} + \frac{H_{o2} - H_{TC}}{\tan \phi_2} + \frac{H_{SB} - H_T}{\tan \theta} + \frac{W_{SB}}{4}$$

Fig. 55. Two-seam pullback range diagram and equation.

$$Re_2 = \frac{H_{SB} - H_T}{\tan \theta} + \frac{H_{o2} - H_{TC}}{\tan \phi_2} + W_{o2}$$

$$H_{SB} = \frac{W_{o2} H_{o1} F_s \frac{(H_T)^2 - (H_{c2})^2}{2 \tan \phi_2} + \frac{(H_T)^2}{2 \tan \theta}}{W_{o1} + \frac{H_{TC}}{\tan \phi_2} + \frac{H_T}{\tan \theta}}$$

$$W_{SB} = W_{o1} + \frac{H_{TC}}{\tan \phi_2} + \frac{H_T}{\tan \theta}$$

$$H_{S2} = \frac{W_{o2} (H_{o1} + H_{o2}) F_s}{W_{o1}} + \frac{W_{o1}}{4} \tan \theta - H_{SB}$$

$$AR = \frac{2 H_{SB} H_T - (H_T)^2}{2 \tan \theta} + \frac{2 H_{TC} H_{SB} - 2 H_{TC} H_{c2} - (H_{TC})^2}{2 \tan \phi_2}$$

Fig. 56. Support equations for two-seam pullback.

Fig. 57. Multiple-seam multiple-bench range diagram and equation.

$$Re1 = W_{o2} + \frac{H_{o2}}{\tan \phi_{o2}} + \frac{H_{c2}}{\tan \phi_c} + W_B + \frac{H_{o3}}{\tan \phi_{o3}} + \frac{[W_{o2} (H_{o2} + H_{o3}) + W_{o3} H_{o1}] F_s}{W_{o1} \tan \theta} + \frac{W_{o1}}{4}$$

Once the actual overburden requirements are ascertained in BCY/year, the first step is to approximate the bucket requirement by dividing the required BCY/year by the production factor (described earlier) of 250,000 (BCY/yr)/(LCYr/cycle).

This ballpark bucket size with the previously calculated effective radius (Re) should narrow down the machine selection to a few models. The productivity equation should be fine-tuned then to include the individualized parameters for the operation, material, and machine cycle times. Manufacturers should provide precise swing times and rope speeds to estimate cycle times for particular models.

Selecting the Dragline: Once the models have been selected and the respective productivities sensitized, separate ownership and operating costs should be calculated and the costs per unit of product compared. This will provide a quantitative comparison and show the least expensive scenario, *if all assumptions are correct*. At this point, check the sensitivity of the parameters and aspects of the plan that would be affected by the unknown, e.g., variances in spoil angle, weather, spoil slides, etc. Finally, assess the credibility of the scenarios; which one takes the most chances, which one is the most feasible? Often this type of qualitative comparison will eliminate the scenario that is favored economically.

DESIGNATION OF VARIABLES

Due to the complexity and variety of conditions that these dragline range equations encompass, it is advantageous to use variable names or designations that are easily and readily recognizable. For that reason, a system of *base* variables with standard designations has been established. These base variables are then subscripted with alpha characters to adapt them and/or subscripted with numeric characters to order them. The base variable set is as follows:

A	Areas
F	Factors
H	Heights
R	Radii
S	Separations
W	Widths
θ	Angles of repose of spoiled materials
ϕ	Angles of repose of in situ materials

The following is a list of the most common variations. Not all variations are listed; however, variable and subscript definitions remain constant and may be mixed as required.

VARIABLES USED IN RANGE EQUATIONS*

AB	Advance Bench (used only as subscript, e.g., H_{AB}).
AR	Area of rehandled material.
B	Bench (used only as subscript, e.g., W_B).
EB	Extended bench (used only as subscript, e.g., W_{EB}).
FS	Swell factor (30% expressed as 1.3).
HC	Height of coal; seams are numerically subscripted in order from top to bottom.
HO	Height of overburden; cuts or interburdens are numerically subscripted in order from top to bottom.
Hs	Height of spoil numerically subscripted in order of placement.
Ht	Height of toe of spoil on highwall measured from pit bottom.
Htc	Height of toe of spoil above the top of the coal.

Rd	Dump radius of designated dragline.
Re	Effective radius of designated dragline.
SB	Spoil bench (used only as subscript, e.g., H_{SB}).
So	Separation from highwall (machine center of rotation to crest of highwall).
Wo	Width of overburden (pit) numerically subscripted from old to new.
θ	Angle of repose of spoil.
ϕO	Angle of repose of highwall numerically subscripted from top to bottom.
ϕC	Angle of repose of coal (in situ) numerically subscripted from top to bottom.

MISCELLANEOUS EXCAVATING TOOLS FOR MINING

FRED R. SARGENT

Backhoes

Backhoes are generally considered secondary tools in the surface mining industry and are at times used for scraping off and cleaning up overlying material from surfaces. The primary use of the backhoe is for construction work such as trenching and excavation of footers for maintenance facilities and office buildings.

The introduction of the large 7.6 to 23-m³ (10 to 30-cu yd) capacity hydraulic backhoes now available to the mining industry has opened many possibilities to improve the handling of overburden or mineral, particularly in coal loading operations. The backhoe allows the choice of locating the truck on top of the overburden or in deep mineral seams, which can be a significant advantage in mines with wet pit floors. As a result, the hoe is easier to service; haul truck ramps are reduced or eliminated; and it may not be necessary to run electrical trail cables into the pit area.

The operating range of a typical hydraulic backhoe equipped with a 12.3-m³ (16-cu yd) capacity overburden bucket or a 17.6-m³ (23-cu yd) capacity coal loading bucket is illustrated in Fig. 58.

If the haul truck loading point can be located in front and slightly to either side of the backhoe, cycle time may be significantly reduced. This is particularly effective in deep seam coal loading when the mine enjoys dry pit floors.

While a dragline may be used similarly to the hydraulic backhoe, the rigid boom and arm of the hoe allow the operator more precise control of the bucket position, which provides more efficient dumping and greater clean coal recovery. See Fig. 59 for standard nomenclature for a hydraulic backhoe.

Clamshells

Clamshells are particularly useful in applications requiring vertical lifting of loose materials from one level to another. A number of operations may require removal of material from a level lower than where the machine sits, or it may be necessary to carry material above the machine.

The clamshell bucket is dumped by releasing the closing line and holding it with the lowering rope. A tag line is used to position the bucket as it is lowered to its digging position and to keep the bucket from spinning.

Some examples of different clamshell uses include opening new canals, cleaning out ditches or settlement ponds, loading from a stockpile into a truck, unloading barges, or loading into a hopper.

Output of Clamshells: The weight of the bucket and the weight of the maximum payload combined comprise the

Fig. 58. Working range of a hydraulic backhoe.

allowable working loads at various radii of operation. These allowable working loads will vary with the percent of tipping designated.

Table 10 shows an allowable working load specification for a specific machine at the various radii of operation. Table

Fig. 59. Hydraulic backhoe nomenclature.

Table 10. Allowable Working Loads, (lb) 5.4-m³ (7-cu yd) (nominal) Clamshell Unit

Radius, ft	Boom Length		
	100 ft	120 ft	140 ft
80	36,000*	36,000*	36,000*
85	36,000*	36,000*	36,000*
90	36,000*	36,000*	36,000*
95	—	36,000*	36,000*
100	—	35,700	35,100
105	—	33,300	32,800
110	—	31,200	30,600
115	—	—	28,700
120	—	—	26,900
125	—	—	25,300

Combined weight of bucket and contents should not exceed values in the table. Values are based on 67½% of tipping, except for those with an asterisk (*), which indicate capacities based on structural competence. Operation is not intended nor approved where allowable load is not shown. Metric equivalents: lb × 0.453 592 4 = kg; ft × 0.3048 = m.

11 gives approximate weights and dimensions of clamshell buckets.

Working Ranges of Clamshells: Fig. 60 shows the lettered dimensions of the working ranges which are generally provided by manufacturers of the various clamshell units.

Production Rate: Example: Assume that a 5.4-m³ (7-cu yd) standard rehandling clamshell bucket will be used to transfer wet sand from a canal into a continuous spoil pile.

Specifications for this calculation:

Boom length	30.5 m (100.0 ft)
Dumping radius	17.9 m (59.0 ft)
Dumping height	20.3 m (66.6 ft)
Digging depth	13.9 m (45.6 ft)
Allowable load, maximum	21 773 kg (48,000 lb)
Hoist speed	1.9 m/s (375 fpm)
Swing speed	3.2 rpm
Bucket size	5.4 m ³ (7 cu yd)
Bucket weight, empty	6872 kg (15,150 lb)
Bucket weight, loaded	15 309 kg (33,750 lb)

The following average cycle time and production are based on:

Dumping height above water level	3 m (10.0 ft)
Average swing angle	90°
Bank yard factor	0.87
Operating hours per day	20

Cycle Time

Closing time to load	6 sec
Hoisting time	9 sec
Swing time	6 sec

Table 11. Approximate Weights and Dimensions of Clamshell Buckets

Size, cu yd	Height Open, ft, in.	Height Closed, ft, in.	Weight of Empty Bucket, lb
3½	11-11	10-2	8,300
4	12-3	10-4	8,855
5	13-8	11-7	11,290
6	14-11	12-4	14,750
7	15-3	12-8	15,150

Metric equivalents: ft × 0.3048 = m; in. × 25.4 = mm; lb × 0.453 592 4 = kg.

Fig. 60. Working ranges of a clamshell crane unit in a barge-mounted application. A, boom angle 40°; B, dumping radius 26m (85 ft); dumping height 15m (50 ft); digging depth 19m (62 ft).

Dumping time	5 sec
Return swing and lower bucket	8 sec
Position bucket	5 sec
Total cycle time	39 sec

Production per Day

Wet sand, lb per bank cu yd	3,500
Bucket fillability	1.00
Size of bucket	5.4 m ³ (7 yd ³)
Total cycle time	39 sec
Cycles/hour	92
Bank cu. yd/cycle	6
Tons/cycle	10.5
Bank cu yd at 100% operating efficiency	552
Operating efficiency-assume	85%
Bank cu yd/scheduled operating hour	469
Tons/scheduled operating hour	821
Bank cu yd/day	9,380
Tons/day	16,420

6.5 Haulage and Transportation

6.5.1 Rail Haulage

R. V. RAMANI

INTRODUCTION

Prior to World War II, rail haulage was the principal type of transportation in large pits. At the present time, in most surface mines, the overwhelming bulk of the mined material is transported from the mine to the crusher by trucks. However, railroad mining at the Morenci mine, Arizona, has been a successful operation since the start of open pit operations nearly 50 years ago (Hoppe, 1977). Here, each day over 136 kt (150,000 st) of ore and waste are hauled by railroad to the ore crusher and waste dumps. The average one-way haul to the crusher is 5.5 km (3.4 miles), and to the waste dumps, 9.3 km (5.8 miles). In the Bingham Canyon mine, Utah, railroad transport has played an important role in handling nearly 454 kt (500,000 st) of ore and waste per day (Jackson, 1980). A continuous blend of new developments with existing equipment has characterized the current materials transport system in Bingham. In 1963, truck haulage began augmenting the all-rail transportation system. In 1977, the conversion of the pit rail system from all electric to diesel-electric was started. As Bingham reaches deeper into the crust of the earth, in-pit crushers and conveyors are planned to replace the rail haulage.

Under favorable conditions, on a cost per ton transported basis, rail haulage is superior to other haulage methods for the transport of mined products to crushers and dumps. The advantage of rail haulage over other methods will dramatically increase with larger haul distances and greater production volumes. Typically, surface mines experience lengthening waste hauls as nearby disposal areas reach their capacities. An increase in length of haul, however, has only limited effect on rail haulage cost.

The most severe requirement for railroad application is the need to maintain a gentle grade for the track. Level grades are obviously the most desirable. Grades of 0.5 to 1% may be regarded as gentle. Relatively steeper grades may be employed within the open pit, a maximum of 3% for uphill hauls and 4% for downhill hauls. Track grades may go as high as 8% or 9% for some mines and industrial applications. The tracks outside the pit, leading to the concentrator or crusher, or the dump can be level or in favor of the load. If loaded trains can operate on level track or on descending grades, substantially lower haulage cost will be realized. However, the haulage cost will not reflect a reduction equal in magnitude to the drop in lift. There will be significant savings in the expense of maintaining diesel engines, wheels, generators, and traction motors. Partly offsetting these savings will be the higher costs of train brake systems maintenance. For the same lift, as the grade is lowered, length of haul increases. For example, a 3% ramp out of an open pit, only 91 m (300 ft) deep, must be almost 3.2 km (2 miles) long. For a 2% ramp, it will be nearly 4.8 km (3 miles). The greater the differences in elevation, the greater are the railroad track grade space requirements.

Capital investment in railroad transport can be considerable. Mines considering this method must have large reserves to support long-life and large production operations.

Also, large areal extent is required to afford greater opportunities for the judicious location of permanent and semi-permanent tracks to minimize track moves. Track moves are not only costly to execute but disruptive to normal mine operations. Figs. 1, 2, and 3 are illustrative of typical track layouts in open-pit mines. Fig. 4 presents a bird's eye view of the track layout in a large open pit mine. Fig. 5 is a close-up showing a shovel loading a train.

Railroad transportation in mines should supplement other transportation methods to develop a materials handling scheme that is best adapted to the general topography, the ore body, and the mining method. In general, where the haul from the mine to the location of processing facilities is over 4.8 or 6.4 km (3 or 4 miles), the topography is generally favorable so that massive earthmoving for railroading is not necessary, and sufficient minable reserves and market are in place for the mined product; the use of a field rail loading point and rail haulage to the processing facility is definitely feasible. In many cases, it is also a desirable alternative. For example, at the Muskingum, OH, mine, a fully automated railroad transports coal 24 km (15 miles) from a truck-unloading field station near the mining area to an unloading and storage facility, which is the beginning of a 7.2 km (4½-mile) belt conveyor system to the Muskingum river power plant (Anon., 1969).

Even in unfavorable topography, if the haul distance is long and the mine life quite high, the application of rail haulage should be explored. The effect of terrain will be severe on track grade construction costs; it is however, rather minimal on the operating costs of rail haulage systems. Specif-

ically, in rolling hills or mountainous territories, the one-time cost of grade construction can be fairly well estimated at the start of the project. The normal service life of railroad equipment is higher than that of most other mine transport equipment. Operating and maintenance costs of tracks, locomotives, and railroad cars will not be significantly affected. Viewed in the context of the repetitive, uncertain, and es-

Fig. 4. Bird's eye view of an open pit mine with rail haulage

Fig. 5. Shovel loading a railroad car in an open pit mine.

calating nature of operating and maintenance costs, rail haulage total costs may not be as severely affected in the future as those of the other transport systems.

This section is restricted to the discussion of railroads in a surface mine. However, dedicated railroads that transport ores from mines to ports or coal to consuming centers are playing an important role in the development of the mineral resources around the world (Anon., 1976; Hoppe, 1977a). In the United States, the unit train concept has been responsible in a large measure for the exploitation of the western coalfields to the benefit of industrial centers in the east and south.

BASIC DESIGN AND EQUIPMENT DATA

The relations of force, matter, and motion are dealt with in the branch of mechanics called kinematics. The understanding of these relationships is essential for the correct design of a rail haulage transportation system.

The accelerating and resisting forces in railroad design are shown in Fig. 6. The resistance to movement comes from many sources, the following being important: locomotive, trailing loads, grade, curve, and acceleration. Adhesion between the wheel tread of the locomotive and the steel rails is responsible for initiating the train movement and sustaining it. Adhesion is determined by rail and wheel material, foreign materials on the wheel tread, wheel diameter, axle weight, and rail condition. Adhesive force that can be developed by the locomotive depends on motor connection, truck characteristics, and wheel slip system characteristics. There are many different formulations to express the fundamental relationships between force, mass, acceleration, velocity, distance travelled, time, and horsepower as a function of the

mine railroad design parameters such as tonnage to be handled, train length and weight, track profile, and locomotive size. The following definitions and formulas illustrate the railroad design procedures.

Rolling Resistance

The resistance to motion offered by the locomotives and the trailing loads depends on such factors as the condition of the track, the kind of bearings on the cars, speed of the train, and rail bending. Rolling resistance is a function of the coefficient of friction between rail and wheel, and the weight of the body in motion; however, it is common to use the specific resistance, instead of the coefficient of friction, to calculate the rolling resistance. Specific resistance is the resistance that must be overcome to move one ton of load, and is expressed in lb per ton. In the railroad industry, there are a large number of formulas recommended for the calculation of specific resistance (Hay, 1982).

The following formulas are provided by Davis (1926):

Locomotive Resistance:

$$R_L = 1.3 + \frac{29}{W} + 0.03 V + \frac{0.0024 AV^2}{WN} \quad (1)$$

Passenger Car Resistance:

$$R_P = 1.3 + \frac{29}{W} + 0.03 V + \frac{0.00034 AV^2}{WN} \quad (2)$$

Freight Car Resistance:

$$R_F = 1.3 + \frac{29}{W} + 0.045 V + \frac{0.0005 AV^2}{WN} \quad (3)$$

where:

W = average weight/axle, tons

N = number of axles

V = speed, mph

A = frontal area, ft²

In general in mine railroads, the contribution from wind resistance may be negligible. The speed of modern-day trains, coupled with the direction of prevailing winds, can have a substantial influence on the total resistance.

Grade Resistance

When a train is moving against a slope, an additional resistance is encountered due to the weight of the train and the grade. Grade is defined as a percent and is the number of feet rise per 100 ft length of track.

Grade resistance in lb per ton of load is given by:

$$(1 \text{ ton})(2000 \text{ lb/ton})(\sin \alpha) = 2000 \sin \alpha$$

where α = the angle of the slope from the horizontal. Since the grade of railroad tracks is rather small, it is generally assumed that $\sin \alpha \approx \tan \alpha$. If grade is expressed in percent, then

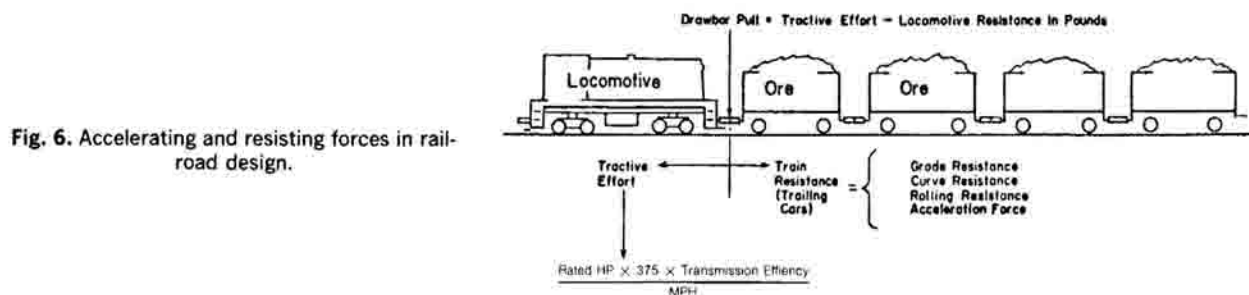

Fig. 6. Accelerating and resisting forces in railroad design.

grade resistance in lb per ton load

$$= 2000 \times \tan \alpha = 2000 \frac{G}{100} = 20 G \quad (4)$$

where G = grade of the track, percent.

Curve Resistance

The resistance due to curves is caused by the slipping of the wheel tires on the rails in the axial direction, the friction between the flange of the wheels and the edge of the rails, and the different lengths of the inner and outer arcs of the rails. The curve resistance depends on many factors such as track gage on the curve, wheel base, wheel diameter, speed, radius of curve, and number of cars on the curve. The following equation from the Plymouth Locomotive Works (Anon., undated) brochure can be used to calculate the curve resistance:

$$\text{curve resistance, lb/ton} = \frac{225 (B + K)}{r} \quad (5)$$

where:

B = wheelbase of the wagons, ft

K = track gauge, ft

r = radius of the curve, ft.

A curve is also defined by its degree. A 1° curve is one in which a hundred feet of track is $1/360$ of a complete circle. The radius of a 1° curve is 5730 ft. Degree of a curve is defined as

$$\text{degree of a curve} = \frac{5730 \text{ ft}}{\text{radius of the curve, ft}}$$

An approximate method for considering the resistance due to curves is to increase the total tractive resistance on level track by 20 to 30%. Another method is to use a resistance of 0.5 to 1 lb per ton per degree of curve. The recommended empirical equation is:

$$\text{curve resistance} = 0.8 \text{ lb per ton per degree of curve.} \quad (6)$$

Acceleration

A moving train consists of parts in linear motion and in rotation. The force required to overcome the inertia of a moving body, i.e., to accelerate or decelerate, can be calculated from the relationship: force = mass \times acceleration, where mass is in lb-sec²/ft and acceleration is in ft/sec². It is common in railroad calculations to express the weight in tons, the force in pounds, and the acceleration in miles per hour per second (mphps). The force required to impart a linear acceleration of 1 mphps to a weight of one ton is calculated as follows:

$$\text{mass} = \frac{(1 \text{ ton})(2000 \text{ lb/ton})}{(32.2 \text{ ft/sec}^2)} = 62.11 \text{ lb-sec}^2/\text{ft}$$

1 mphps acceleration

$$= \frac{(1 \text{ mile})(5280 \text{ ft/mile})}{(1 \text{ hour})(3600 \text{ sec/hour})(\text{sec})} = 1.47 \text{ ft/sec}^2$$

$$\text{force} = \text{mass} \times \text{acceleration} = 62.11 \times 1.47 = 91.3 \text{ lb}$$

To allow for the acceleration of the mass in rotary motion, the calculated force must be increased between 5 to 10%. Thus, the total acceleration force required to impart a linear acceleration of 1 mphps and the needed rotational acceleration for the wheels, motors, and gears is approximately 100 lb per ton. Thus, if T is the weight of the train in tons and a is the linear acceleration in mphps, then the accelerating force (F_a) required is:

$$F_a = 100 a T \text{ lb} \quad (7)$$

Adhesion

Adhesion or coefficient of friction is defined as attachment between the wheel tires of the locomotive and the rail. The pulling force or the tractive effort a locomotive can deliver depends on the coefficient of friction between the wheel and the rail. It is a function of the material of the wheel tires and the rail; the conditions of the rail, whether wet, dry, or sanded; and to some extent on the springing and center of gravity of the locomotive. Adhesion is expressed as a percent and is defined as:

$$\% \text{ adhesion} = \frac{\text{available tractive force (lb)}}{\text{total weight on drivers (lb)}} \times 100 \quad (8)$$

$$\text{Available tractive force, lb} = \left(\frac{\% \text{ adhesion}}{100} \right) (\text{total weight on the drivers, lb}) \quad (9)$$

Adhesion values should be determined from a careful study of the conditions in the mine. Values for conditions usually encountered in mines are shown in Table 1 (Staley, 1949; Szklarski, Dudek, and Machowski, 1969). A starting adhesion of 25 to 30% can be attained. For a locomotive on the run, the values of adhesion are somewhat lower; running adhesions of 18 to 20% are normally attainable under average rail conditions. Higher running adhesions, up to 25%, are possible under excellent conditions. A locomotive speed-tractive effort curve provides the values of tractive effort that the locomotive can generate at different speeds. The curve for a 45-ton locomotive is shown in Fig. 7. Locomotive speed-tractive effort charts are available from the manufacturers.

Net Tractive Effort

This is defined as the difference between the available tractive effort and the various resistances to train movement. The net tractive effort is the force that creates acceleration.

Table 1. Adhesion Between Locomotive Wheels and Level Track (Percent)

Conditions	Wheels	
	Chilled Cast Iron	Steel Tires or Wheels
Dry rails, with sand	25	33
Dry rails, no sand	20	25
Moist rails	15	20
Wet rails	5-10	5-15

Fig. 7. Locomotive speed-tractive effort chart.

Balancing Speed

The speed at which the net tractive effort is zero is called the balancing speed. At this speed, all the available tractive effort is used to overcome the various resistances to train movement, leaving no tractive effort for acceleration.

Useful Formulas

The following general transportation formulas are summarized from the earlier discussion.

$$\begin{aligned} \text{Acceleration (mph/sec)} \\ &= \frac{\text{net tractive effort (lb)}}{100 \times \text{weight of trains (ton)}} \end{aligned} \quad (10)$$

$$\begin{aligned} \text{Time for which acceleration} \\ \text{is assumed constant (sec)} \\ &= \frac{\text{change in speed (mph)}}{\text{acceleration (mph/sec)}} \end{aligned} \quad (11)$$

$$\begin{aligned} \text{Distance travelled (ft)} \\ &= 1.467 \times \text{average speed (mph)} \times \text{time (sec)} \end{aligned} \quad (12)$$

$$\begin{aligned} \text{Distance travelled (miles)} \\ &= 0.000278 \times \text{average speed (mph)} \times \text{time (sec)} \end{aligned} \quad (13)$$

$$\text{Time (minutes)} = \frac{\text{distance (miles)}}{\text{average speed (mph)}} \times 60 \quad (14)$$

$$\begin{aligned} \text{Trailing load (tons)} &= \left[\frac{\text{tractive effort (lb)}}{\text{total resistance (lb/ton)}} \right] \\ &\quad - [\text{locomotive weight (tons)}] \end{aligned} \quad (15)$$

$$\begin{aligned} \text{Rail horsepower} \\ &= \frac{\text{tractive effort (lb)} \times \text{speed (mph)}}{375} \end{aligned} \quad (16)$$

$$\begin{aligned} \text{Horsepower input to generator} \\ &= \frac{\text{rail horsepower}}{\text{efficiency of the transmission}} \\ &\quad (\text{generator} + \text{motor}) \end{aligned} \quad (17)$$

$$\begin{aligned} \text{Engine horsepower} \\ &= \text{horsepower input to generator plus} \\ &\quad \text{allowances for auxiliaries (radiator,} \\ &\quad \text{fan, air compressor, etc.)} \end{aligned} \quad (18)$$

$$\text{Gear ratio (G.R.)} = \frac{\text{Number of teeth on gear}}{\text{Number of teeth on pinion}} \quad (19)$$

$$\text{Motor rpm} = \frac{336 \times \text{speed (mph)}}{\text{wheel diameter (in.)}} \times \text{G.R.} \quad (20)$$

Braking

In addition to knowing the capacity of a locomotive for starting and hauling a train, its ability for stopping the train should be considered. When power is cut off to the locomotive, there is an accumulated reserve of kinetic energy in the train, which is used to overcome the resistance to motion. Under *favorable* conditions, the velocity of the train will drop and the train may come to a stop by coasting. The distance over which the train will come to a stop depends on the rate of drop of velocity (or deceleration). However, when taking load *down* a grade, there usually is no deceleration even after the power is cut off to the locomotive. In fact, the train may tend to accelerate rather than slow down. From the practical point of view of positive control over the train movement, braking requirements and performance must be investigated. The value for adhesion during braking is assumed to be 80 to 85% of that during hauling. Consequently, the braking effort is 80 to 85% of the tractive effort.

Stopping Distance and Time

The retarding force (F_r) is the sum of the braking effort, the train resistance, and the grade (combined with curve) resistance. An ascending grade aids retardation; a descending grade reduces retardation.

$$\begin{aligned} F_r &= \text{braking effort} \\ &\quad + \text{rolling resistance} \pm \text{grade resistance} \end{aligned} \quad (21)$$

Knowing the retarding force, the theoretical stopping distance, and the theoretical time to stop can be calculated as follows.

$$\begin{aligned} \text{Kinetic energy of the train at the time of braking} &= \\ \frac{1}{2} mv^2 &= \frac{1}{2} \frac{w}{g} v^2 \end{aligned}$$

where w = weight of the train, lb

v = velocity, ft/sec

g = acceleration due to gravity, ft/sec²
= 32.2 ft/sec²

If S is the stopping distance (ft), and the retarding force is F_r (lb), then

$$\text{work done} = F_r \times S$$

and

$$F_r \times S = \frac{1}{2} \frac{w}{g} v^2$$

$$S = \frac{1}{2} \frac{w}{F_r} \frac{v^2}{g}$$

Expressing w and v in practical units of tons (W) and mph (V),

$$S = \frac{1}{2} \left(\frac{W \times 2000}{32.2} \right) \times \left(\frac{5280}{3600} \right)^2 \frac{V^2}{F_r} = 66.8 \left(\frac{WV^2}{F_r} \right)$$

The rotary parts of the train also will have some kinetic energy. Assuming this to be approximately 5% of the linear component, the stopping distance can be increased by the same amount, i.e.,

$$S = \frac{70 WV^2}{F_r} \quad (22)$$

The stopping distance S can also be expressed as the product of the average velocity during the stopping time, and the stopping time, t , i.e.,

$$S = \left(\frac{V}{2}\right)(t)$$

where t = stopping time, seconds.
Since

$$F_r \times S = \frac{1}{2} \frac{w}{g} v^2$$

$$F_r \times \frac{v}{2} \times t = \frac{1}{2} \frac{w}{g} v^2$$

$$t = \frac{wv}{gF_r}$$

As before, expressing the weight and velocity in practical units of tons and mph, respectively, and increasing the stopping time by 5% to account for the kinetic energy in the rotating components,

$$t = \frac{W(2000)}{(32.2)} \left(\frac{5280}{3600}\right) \left(\frac{V}{F_r}\right) (1.05) = \frac{95.6 WV}{F_r} \quad (23)$$

In practice, the stopping distance and time vary due to many factors. The rate and time of propagation of brake application vary. The differences due to the human element are ever present. In fact, the above theoretical values should be increased by 25 to 30% for these and other safety reasons (Hay, 1982). Where the braking distances are critical, they should be established by tests.

The stopping distance and time formulas are generalized below for both acceleration and deceleration from one speed to the next.

If the train accelerates from a velocity V_1 to a velocity V_2

$$\text{Acceleration time, sec} = \frac{95.6}{NTE} (V_2 - V_1) \quad (24)$$

$$\text{distance, ft} = \frac{70}{NTE} (V_2^2 - V_1^2) \quad (25)$$

where NTE = net tractive effort available for acceleration, lb. If the train decelerates from a velocity V_2 to a lower velocity V_1 ,

$$\text{deceleration time, sec} = \frac{95.6}{F_r} (V_2 - V_1) \quad (26)$$

$$\text{distance, ft} = \frac{70}{F_r} (V_2^2 - V_1^2)$$

where F_r = retarding force, lb.

Example 1: Calculate the size of a locomotive (weight in tons) to start and haul a load of 350 tons at 4 mph up a gradient of 1%. The track is 4 ft-8½ in. gage and has a minimum curve of 200 ft radius which coincides with the gradient. The wagons have a wheel base of 9 ft-6 in. The maximum acceleration specified is 0.1 mphps. Adhesion is 25%. Assume a train and locomotive rolling resistance of 20 lb per ton.

Solution: Let L be the weight of the locomotive in tons.

$$\text{Available tractive effort, lb} = \left(\frac{25}{100}\right)(L)(2000) = 500L$$

$$\begin{aligned} \text{Total resistance, lb} &= \text{rolling resistance of the locomotive and the trailing loads} \\ &+ \text{grade resistance of the locomotive and the trailing loads} \\ &+ \text{curve resistance} \\ &+ \text{resistance due to acceleration} \\ &= 20[L + 350] + 20 \times 1 \times [L + 350] \\ &+ \frac{225 [4 \text{ ft } 8\frac{1}{2} \text{ in.} + 9 \text{ ft } 6 \text{ in.}]}{200} \times [L + 350] \\ &+ 100 \times 0.1 \times [L + 350] \\ &= 65.98L + 7000 + 5593 + 7000 + 3500 \\ &= 65.98L + 23093 \\ 500L &= 65.98L + 23093 \\ L &= 53.21 \text{ tons} \approx \text{select a 54-ton locomotive.} \end{aligned}$$

The speed-tractive effort curve of the selected locomotive should be such that it will develop approximately 26,655 lb of tractive effort at 4 mph.

$$\begin{aligned} \text{Rail horsepower} &= \frac{54 \times 0.25 \times 2000 \times 4}{375} \\ &= 288.0 \end{aligned}$$

$$\text{Hp input to generator assuming 80\% efficiency} = \frac{288.0}{0.8} = 360.0$$

$$\text{Engine horsepower allowing 15\% for accessories} = \frac{360.0}{0.85} = 423.5$$

Example 2: Determine the number of 30-ton, four-axle cars that can be hauled by a 45-ton diesel electric locomotive at 10 mph up a 0.2% grade through an average track curve of 2°. The rolling resistance for the locomotive is 5 lb/ton and for the cars, 10 lb/ton. The speed-tractive effort curve of the 45-ton locomotive is shown in Fig. 7.

Solution: The tractive effort at 10 mph can be read from the curve in Fig. 7 as approximately 7500 lb.

$$\begin{aligned} \text{Total resistance of the train} &= \text{rolling resistance} \\ &+ \text{grade resistance} \\ &+ \text{curve resistance} \end{aligned}$$

Let N be the number of cars that can be hauled.

$$\text{Total weight of the train} = (45 + 30N)$$

$$\text{Rolling resistance} = (45 \times 5) + (30N)(10) = 225 + 300N$$

$$\text{Grade resistance} = (45 + 30N)(20)(0.2) = 180 + 120N$$

$$\text{Curve resistance} = (45 + 30N)(0.8)(2) = 72 + 48N$$

$$\text{Total resistance} = 477 + 468N$$

For balancing speed,

$$\begin{aligned} \text{Tractive effort} &= \text{total resistance} \\ 7500 &= 477 + 468N \end{aligned}$$

Therefore, $N = 15$ cars.

Example 3: A locomotive weighing 45 tons is hauling 450 tons down a straight gradient of 1 in 100 at 4 mph. Percent adhesion during braking is 15. The rolling resistance is 12 lb/ton for the locomotive and for the trailing load. Calculate the stopping distance and the stopping time.

Solution: Retarding force, F_r = braking effort + rolling resistance ± grade resistance

The grade in this instance will assist the train movement, and decrease the retarding force.

$$\begin{aligned}
 Fr &= \left[45 \times 2000 \times \frac{15}{100} \right] + [45 + 450] [12] \\
 &\quad - [45 + 450] [2000] \left[\frac{1}{100} \right] \\
 &= 13500 + 5940 - 9900 \\
 &= 9540 \text{ lb.} \\
 S &= \frac{70 WV^2}{F_r} = \frac{70 \times 495 \times (4)^2}{9540} = 58.11 \text{ ft} \\
 t &= \frac{95.6 WV}{F_r} = \frac{95.6 \times 495 \times 4}{9540} = 19.84 \text{ sec.}
 \end{aligned}$$

When a train starts from rest, the tractive effort available is maximum. The net tractive effort is also maximum and contributes to accelerate the train. As the train accelerates and gains speed, the tractive effort decreases, and so does the net tractive effort; when net tractive effort is zero, balancing speed is achieved. The rate of change of acceleration is not uniform, and depends on the speed of the train and the resistance; therefore, the speed-time-distance calculations become important. A complete haul of a train may involve a series of acceleration and braking cycles. The following example illustrates the method of calculating the speed-time-distance data.

Example 4: Consider the case of a 65-ton locomotive whose speed-tractive effort chart is shown in Fig. 8. The train is powered by four traction motors. The ampere-tractive effort curve for one of the motors is shown in Fig. 9. The locomotive hauls eight 35 ton cars. The train has to haul up a grade of 0.5% on a straight track with no curves. The locomotive and train rolling resistances are 10 lb/ton. The train starts from rest and when a speed of 12 mph is reached, the power is cut off and the train is braked at a uniform rate of 1 mph/s. Calculate the distance travelled, the elapsed time from start to stop, and the continuous current rating of the motor.

Solution:

Total load = $(65 + 8 \times 35)$ tons = 345 tons
 Train resistance = $345 \times 10 = 3450$ lb
 Grade resistance = $345 \times 20 \times 0.5 = 3450$ lb
 Curve resistance = 0 lb
 Total resistance (excluding acceleration) = 6900 lb

Fig. 8. Speed-tractive effort chart for a 59-t (65-ton) diesel-electric locomotive.

Fig. 9. Ampere-tractive effort curve for a tractive motor.

The speed-time-distance calculations for this problem are best done in a tabular form as shown in Table 2. It is convenient to increase the speed from rest in increments of 2 mph, though smaller or larger increments may be used for greater or lesser accuracy, respectively.

Since there are four motors on the locomotive, each motor contributes to one-fourth of the total tractive effort of the locomotive. The calculations for the continuous current rating are also best performed in a tabular manner as shown in Table 3. Entries in columns 1, 2, 3 and 6 of Table 3 are obtained from Table 2, columns 1, 2, 7, and 10, respectively. Entries in column 4 are obtained by dividing corresponding entries in column 3 by the number of motors, which is 4 in this case. Entries in column 5 are obtained from Fig. 9, using entries in column 4 as the entry points.

$$I^2 = \frac{I_1^2 d_{t_1} + I_2^2 d_{t_2} + I_3^2 d_{t_3} + \dots}{T} \quad (28)$$

where

I = the continuous current rating of the motor, amperes
 d_{t_i} = the time required to traverse the track section at the average speed (see explanation for Column 10 in Table 2), sec
 I_i = the current drawn by the motor for the tractive effort required, obtained from the ampere-tractive effort curve of the motor, amperes
 T = the total elapsed time from the start and to the stop of the motor,

$$\begin{aligned}
 I^2 &= \frac{3,304,038}{116.28} = 28414.50 \\
 I &= 168.57 \text{ amperes}
 \end{aligned}$$

In summary, from start to stop, the train took 116.28 seconds and travelled 1515.7 ft. The required current rating of each of the four motors should be greater than 169 amperes.

The above examples are meant to be illustrative of the application of the design formulas to planning and engineering problems. In practice, computerized calculation procedures are recommended for evaluating railroad designs. Railroad computer programs include not only speed-time-distance calculations but several other factors such as fuel consumption and continuous current rating calculations. There is no need to make simplifying assumptions for ease in calculations. Many alternatives to a railroad design problem can be evaluated. The design can be optimized with

Column 1 - Speed in mph taken at 2 mph increments.

Column 2 - Average speed during speed change.

Column 3 - 4 and 5 are self explanatory.

Column 6 - The sum of columns 3, 4, and 5.

Column 7 - Locomotive tractive effort, obtained from the speed-tractive effort curve for the 65-ton locomotive at the speed shown in column 2.

Column 8 - Net tractive effort available for acceleration (column 7 minus column 6).

Column 9 - The acceleration obtained by dividing the net tractive effort available for acceleration by the product of 100 and the total weight of train with locomotive (see equation 10).

Column 10 - Time in seconds required to effect the change in speed shown in column 1, under the accelerating shown in column 9. The time is obtained by dividing the increment in speed in column 1 by the acceleration shown in column 9 (see equation 11).

Column 11 - The summation of time increments under column 10.

Column 12 - The distance in feet travelled in the time increment of column 10 at the average speed shown in column 2 (see equation 12).

Column 13 - The total distance covered, in feet.

$$T = 116.28$$

$$\Sigma I^2 d_t = 3,304,038$$

respect to any chosen parameter such as energy consumption and run time. Railroad simulation programs are available from several sources including manufacturers and consulting engineering companies.

EQUIPMENT AND TRACK

The pulling force to overcome the resistance to motion is provided by a locomotive. The pulling force or the tractive effort generated by a locomotive is a function of its horsepower and its speed:

$$TE = \frac{(375)(hP_e - hP_a)(\eta)}{(V)} \quad (29)$$

where

TE = tractive effort or pulling force, lb
 hP_e = horsepower of the locomotive engine shaft
 hP_a = horsepower to the auxiliaries
 V = speed of the locomotive, mph
 η = transmission efficiency, usually between 0.80 to 0.85

Using an η of 0.82,

$$TE = \frac{(308)(hp)}{V} \quad (30)$$

where hp is the manufacturer's rated horsepower for the locomotive.

Industrial locomotives may be for gages from 18 to 66 in., and railroad locomotives may be for gages of 24 to 66 in. The profile of the track, the maximum grade to be encountered, the number of cars and the weight of the cars will determine, as explained before, the size of the locomotive. There are many types of railroad cars—gondola cars, box cars, hopper cars, tank cars, etc. The cars can be bottom-dump or side-dump; about 80% of the cars in use today are bottom-dump hopper cars. Gondola cars are restricted to hauling ore to the crushers. Cars to haul ore and waste in open pit mining are built more substantially than regular cars and may require special mechanisms to facilitate dumping. Ample tractive effort must be available to pull the train over the grade without slipping, which occurs when the tractive effort at the wheels exceeds the available adhesion between the wheels of the locomotive and the rail. Once a locomotive has been selected, the train size will be dependent on operational factors such as the overall adhesion and the condition of the track.

There are many possible prime movers for the locomotive. The common prime movers are diesel, diesel-electric, and electric. Steam engines were widely used in the past. Efforts are continuing to develop new prime movers which are in experimental stages such as steam turbine, oil-gas, and coal-gas turbines. Discussion here will be limited to diesel-electric and electric locomotives.

A diesel-electric locomotive is essentially an electric locomotive with a self-contained power plant, the diesel engine-generator combination. Compared to diesel-electric, an electric locomotive has more horsepower per ton weight ratio and greater adhesion. Electric models (25 kV or 50 kV, 60 Hz) with over 6000 hp are available. They can be of four or six axle designs. Diesel electrics provide 3000 to 3600 hp per unit and there are a few 5500-hp experimental units. An electric locomotive is obviously limited to those tracks with a power supply, a third rail or a catenary. An electric locomotive costs considerably more than a diesel-electric but it has a much longer life, nearly twice that of the 15 to 20 years first life (before rebuilding) of the diesel engine. The

availability of the electrics is also higher, about 95%. Diesel-electrics availability will average about 85% because of servicing and engine repairs. Overall maintenance costs for electrics can be one-half to one-quarter of those for diesel electric. With electrics, there is no fuel storage and handling, and no water treatment or freeze-up problems. The electric operation is clean and nonpolluting.

There are a number of requirements with electrification. Direct current (D.C.) locomotives are not generally available and are usually of a special design. Rail bonds have to be increased in size and interference problems with other way-side systems must be studied. The interference factors with the power supply such as unbalanced voltage or current (because the locomotive is a single-phase load), power factor (varies with locomotive design and catenary impedance), harmonic currents (due to phase control system on the locomotive), and peak power demand must be studied (Henderson, 1983). The choice of diesel-electric or electric locomotive is very application dependent and cannot be generalized. Diesel-electrics have proven operating experience in industrial and mining applications. In several surface coal mines, however, the transport of coal from the mine to the power plant is achieved with dedicated high-speed electric railroads. Table 4 lists some salient statistics on rail haulage applications in open pit mines.

The railroad track is a complex structure put together with a few components. It supports the train load and guides the train movement. Safety, dependability, and performance of a railroad are determined by the condition of the track, which is subject to a variety of static and dynamic loads. It is a flexible load-distributing structure requiring great care during construction on such matters as rail size, ties, alignment, subgrade, ballast, drainage, track surface, track geometry, and rail joints. Reference has already been made to track grades. In mines, track grades may go as high as 8 to 9%. Track curves may be 35-ft in radius (degree of the curve = $5730/35 = 164^\circ$). One way to reduce the centrifugal force on a curve is to reduce the train speed on the curved track. Another way is to raise the outside rail as much as 4 in. over the inside rail around the curve. This height of the outside rail above the inside rail is called *superelevation*. The superelevation of the outside rail can be calculated from the formula,

$$h = \frac{av^2}{gR}$$

where

h = superelevation, ft
 a = the rail gage, ft
 v = velocity, ft/sec
 g = acceleration due to gravity, ft/sec²
 R = radius of the curve, ft.

Expressing the velocity in mph (V), h in inches, and the curve in degrees ($D = \frac{5730}{R}$),

$$h = \frac{a \times \left(\frac{5280}{3600}\right)^2 \times V^2}{32.2 \times \left(\frac{5730}{D}\right)} [12] = 0.00014aDV^2 \quad (31)$$

where

h = superelevation, in.
 V = speed, mph
 D = degree of the curve.

Table 4. Surface Mines Utilizing Rail Haulage, 1966

Name of mine	Name of Company	Location	Type of ore	Locomotive data			Car sizes (st)	Cars per train	Average haul distance loaded (ft)	Continuous grade (%)
				type	hp	wt (tons)				
Chuquicamata	Chile Exploration Co.	Chuquicamata Chile, SA	Copper	Diesel-electric	1200 1750	120&190 (used as pushers)	68.5	14	10,000 (ore and waste)	+3
Erie	Erie Mining Co.	Hoyt Lakes, Minnesota, US	Tacopite	Diesel-electric	1200 1800 2000 2400	124 130 134 128	95	9	39,000	+2

Morenci	Phelps Dodge Corp.	Morenci, Arizona, US	Copper	Diesel-electric	1750 1800	130	83	11	21,000	+3 & -4
New Cornelia	Phelps Dodge Corp.	Ajo, Arizona, US	Copper	Diesel-electric	1750 2250	125&140	65&62 65&62	7 8	22,000 22,000	+3 +3
Bingham	Kennecott Copper Corp.	Bingham, Utah, US	Copper	Electric	1200 1600	85&125	86.5 (ore) 73 (waste)	14-21 (ore) 8 (waste)	35,000 (ore) 25,000 (waste)	-5 -5
Toquepala	Southern Peru Copper Corp.	Toquepala, Peru, SA	Copper	Diesel-electric	1800	135	83	10	17,000 (ore) 13,000 (waste)	-4
Kounrad		Kazakhstan, USSR	Copper	Electric	?	150	95&100	5	? (ore) 18,000 (waste)	+3

A combination of reduced speed and superelevation is used to counteract the centrifugal forces on curves.

MINE RAILROAD SAFETY

Mine railroads present unique operational and maintenance problems. Many commercial railroad practices are not directly applicable to mine railroads because of the conditions under which the tracks and equipment are used. The duty cycles for the mine locomotives and ore and waste cars are different. Within the mine, the track location is semipermanent. Frequent track shifts and additions and deletions are necessary. On the waste dumps, the track will be shifted to a new crest when dumping becomes increasingly difficult from existing locations. The subbase material for mine railroads may be weak, particularly on the waste dumps. The ballast material is usually crushed rock from the mine. Fortunately, mine trains operate at comparatively low speeds. However, the loss of safety and efficiency that can result from poor railroad systems requires that great care be exercised in the design, construction, inspection, and maintenance of mine railroads. Also, records of inspections and all track and train problems are essential for improvement of track safety. The discussion hereafter generally follows that by Brauns and Orr (1968).

Rolling Stock Maintenance

Adequate repair shops for locomotives and cars are essential. Except for its arrangement, a locomotive shop should

be as well-equipped as a modern repair shop for off-highway trucks. Other maintenance work on locomotives logically divides itself into two horizons. That on brake systems, traction motors, etc. is most easily performed at track level. Work on the engines, generator, air compressor, and other components mounted atop the frame is best performed from the level of the frame or deck. Platforms at that level are a great convenience to mechanics. Minor repairs and overhauls are best accomplished in a shop building designed for the purpose. Automatic welding equipment for body work is very desirable. For any extensive body repair or rebuilding work, equipment for cutting and forming large steel plates is essential.

Track Maintenance

Track maintenance is vital to an efficient rail haulage system. Good alignment and surface on main line tracks is necessary if trains are to travel rapidly. Rough track not only slows the train but contributes greatly to the damage of rolling stock, crossties, and rail wear. This is normally the largest element of rail haulage cost, sometimes amounting to as much as 50% of that cost.

Guidelines for the construction, inspection, and maintenance of underground rail haulage track are presented in a research report to the US Bureau of Mines (Cunney, Rudd, and Hawkins, 1977). Many of these guidelines should be useful to the surface mine rail haulage tracks as well. A track maintenance program is usually offered by a manufacturer

of rail products (Anon., 1980). The program includes a system for identifying existing and potential trouble spots, and setting timetable priorities for eliminating them.

A number of track maintenance machines have been developed for the common carrier railroads in recent years which are very useful in pit track work. Some of these are tie tampers, power jacks, ballast distributors and shapers, track liners, tie spacers, spike drivers, and bolt tighteners. Tampers and lining machines have recently been provided with controls capable of bringing track automatically to a present grade and line.

Rail Waste Dumps

These are more expensive to establish and maintain than are truck waste dumps. A grade must be prepared upon which track can be laid to initiate the dump. The initial track should be at least a train length long, and it is preferable that it extend for several train lengths. Dump height is largely dictated by the type of terrain available for waste disposal. Dumps in mountainous areas are likely to be high, while those in areas of little relief are generally low. High dumps require less frequent track throws, but they are more susceptible to settlement. Preventing the track from developing excessive grades as a result requires continual work. Rail dumps routinely develop a berm along their crests as the dumped material builds out from the track. When the berm becomes sufficiently high to seriously impede the action of muck sliding out of a dump car, the dump is said to be *plugged*. It is then necessary to blade off the berm and shift the track out to the new crest.

Waste trains are commonly pushed onto dumps rather than pulled. This is a precaution to save the locomotive from the likelihood of derailment and from the rare possibility that the dump crest may slough. More derailments occur on dumps than in any other part of a pit track system. Track quality is necessarily only fair because the track receives considerable abuse from frequent moves and derailments. Material covers the outside rail as the plug develops, frequently causing cars to jump the track.

Traffic Control Systems

For two or more trains to operate on a single track safely, some means of regulating traffic is needed. Simple manually operated signals suffice where only two trains are involved, or in the case of one train operating under conditions of restricted speed and clearance, as when track is being repaired. Automatic block-signal systems are a very effective means of regulation. Blocks are sections of track electrically bonded so as to form complete circuits, and these are connected to light signals. In single-track territory, the signal indications in the blocks both in front of and behind an occupied block will likely be stop. The signal in the block behind may display an approach aspect, meaning proceed at reduced speed and be prepared to stop at the next signal. Block signals on a single track can control traffic in one direction only. Two-way traffic can be accommodated if passing tracks are located at convenient intervals, and for most efficient operation two tracks are required. Many mine trains are equipped with two-way radios for communications between engineman, supervisors, and maintenance men. These radios also afford a means of traffic control.

Where train traffic is dense, a centralized traffic-control (CTC) system is superior to all other types of systems. CTC is unequalled in its ability to handle trains rapidly and safely over a given stretch of track. The operator, working from a control panel containing a diagram of the tracks in the system, selects the route of each train. Lights on the panel

indicate the positions and movements of the trains as well as the aspects of the signals and positions of the switches. Signals either along the wayside, in the locomotive cab, or sometimes both, convey information to the locomotive engineer how a train is to proceed along the route.

Automated Operations of Trains

Within the past few years there have been revolutionary developments in the field of automatic train operation. Much experimental work is being conducted with a view to improving automation of commuter trains. Undoubtedly this will also benefit rail haulage in making available to mine managers a choice of several modes of automatic train control.

Three types of systems are remote control, supervisory control, and programmed control. At least two of the types have been applied to surface mine railroads. Radio remote-control systems are in use at the Morenci and New Cornelia mines. Wired remote control is more easily applied to electric locomotives. Supervisory control has train movement controlled by dispatcher who directs train movements between various points. The operator directs the train movements from point to point but the protection against conflicting moves, the speed of train movement, and train safety are built into the system, thus freeing the dispatcher for major operations only. The programmed-control system has no planned manual supervision. Some systems are in operation in which a sequence of events is performed during a complete cycle while in others, part of a cycle must be completed before the rest of the cycle can proceed. Provision is made for overriding control of the program so that an operator or maintenance man can correct a defect or stop operation at any time.

RAILROAD COSTS

The procedures for estimating the costs of a surface mine railroad are no different from those used for any other industrial activity. The basic requirements for getting dependable results are (1) developing accurate production data, (2) performing good engineering and design calculations, (3) estimating correctly the capital and operating costs, and (4) following a well-accepted costing procedure. Cost information from prior projects can be useful in the estimation process but too much reliance should not be placed on these. Railroads have a large initial investment in tracks, yards, structures, signals, and car and locomotive fleet. Significant cost changes from prior years can therefore occur due to changes in technology. Secondly, major railroad jobs like earthwork and trackwork are very site dependent. The influence of the site conditions, such as topography and slope, transcends both capital and operating costs. The construction costs per mile of track can vary from \$100,000 to \$1,000,000 or more.

The election of diesel-electric vs. electric locomotives has similar effects. The initial cost of a 65-ton to 144-ton, four axle diesel-electric switching locomotive with 600 to 1100 hp motor is between \$500,000 to \$700,000. Diesel-electric surface traction locomotives cost from \$900,000 to \$1,200,000 each. The lower maintenance, greater availability, and larger life of electric locomotives combine to lower the number of electrics required for a given production. However, electrics initial costs are higher. A 6000 hp, 190-ton electric locomotive costs nearly \$2,000,000.

It is also important to develop appropriate units for evaluating costs of the various alternatives. Unit costs used by the US railroad companies include the cost per train mile,

the cost per revenue ton mile, cost per locomotive mile, and cost per track mile maintained. For commercial railroads, accounting rules are prescribed by the Interstate Commerce Commission (ICC). ICC statistics may be useful for estimating some operating costs such as those for track maintenance (Poole, 1962).

In practice, good planning, engineering and design procedures should determine the various construction requirements, equipment specifications, personnel requirements, operating performances, and usage of principal supplies. For example, earthwork and trackwork must be calculated from the engineering drawings. Equipment requirements must be based on the production and mining plan. Fuel consumption should be obtained from the speed-time-distance calculations. Costs associated with the maintenance of rolling stock (locomotives and cars) and track account for a major fraction of the total operating costs, as much as 60 to 80%. Correct estimation of these is important. The reliability of the cost estimates can be greatly improved by working closely with manufacturers and suppliers. The following estimating procedure is useful to determine the cost of ownership and operation.

Cost of Ownership

The capital investment in a mine railroad will include cash outlays for such items as right-of-way acquisition, tracks, structures, signals, locomotives, and cars. The cost of railroad cars is between \$40,000 to \$50,000 per car. The cost is variable depending on the type of car and attachments put on it to facilitate loading, hauling, and dumping. The investment will consist of the labor, equipment, and materials associated with the following:

1. Land surveys and all construction engineering.
2. Land and land damages, including right-of-way acquisition.
3. Earthwork such as clearing and grubbing, earth and rock excavation.
4. Construction of culverts, bridges, and trestles.
5. Trackwork such as rails, ties, and switches.
6. Buildings such as repair shops, engine houses, and tool houses.
7. Communications and signalling.
8. Equipment, locomotives, cars, and any other specialized equipment such as those for track inspection.

The costs of ownership consists of two components, (1) depreciation of the investment due to wear and tear during use, and (2) cost of interest, taxes, and insurance.

Depreciation: The calculation of depreciation requires an estimation of the useful life of the investment item, i.e., an estimation of the life of the track, locomotives, cars, etc. In the United States the Internal Revenue Service provides depreciation guidelines and rules. For such preliminary cost estimation as discussed here, it is sufficient to use a straight line depreciation with no allowance for investment tax credit. Annual depreciation costs for each capital item will be calculated as follows:

$$D_i = \frac{I_i}{L_i} \quad (32)$$

$$D = \sum_{i=1}^N D_i \quad (33)$$

where

- D_i = annual depreciation on capital item i , dollars
 I_i = total investment in capital item i , dollars
 L_i = life of item i , years

D = annual depreciation, dollars

N = number of capital items ($i = 1, 2, \dots, N$)

Interest, Taxes, and Insurance: The interest costs account for the cost of using capital to construct the railroad and to purchase equipment and facilities. As a result of ownership, there will also be costs of insurance and property taxes. Annual interest, taxes, and insurance costs are usually calculated as a percentage of the average investment in the equipment. The average investment is based on the number of years used for depreciation.

$$P = \text{Int} + \text{Tax} + \text{Ins}$$

$$T_i = \left(\frac{1}{2}\right) \left(\frac{L_i + 1}{L_i}\right) \left(\frac{P}{100}\right) (I_i) \quad (34)$$

$$T = \sum_{i=1}^N T_i \quad (35)$$

where

P = factor for interest, taxes, and insurance, percent

Int = interest rate, percent

Tax = property taxes, percent

Ins = insurance rate, percent

T_i = annual interest, taxes, and insurance costs for the capital item i , dollars

T = annual interest, taxes, and insurance costs, dollars.

Yearly cost of ownership is given by

$$R = D + T \quad (36)$$

where R = yearly ownership costs, dollars.

Operating Costs

According to an analysis of the 1978 US railroad operating costs, maintenance of equipment accounted for 26% of the total operating costs; maintenance of way and structures, 19%; transportation costs, 46%; and general and administrative expenses, 9%. Although these figures are not applicable to mine railroads, this breakdown provides a rational basis to categorize mine railroad operating costs.

1. Maintenance of way and structures includes all costs of maintaining the *fixed plant* such as tracks, terminals, and signals. Materials and labor constitute the major cost items.

2. Maintenance of equipment covers the repairs to locomotives, cars, and maintaining workshop facilities.

3. Transportation category includes all costs associated with running the trains, yards, terminals, signals, and other expenses involved in the direct operation of the railroad. Labor and locomotive fuel, in that order, are the most important cost components in nonautomated railroads.

4. General and administrative costs are expenses associated with the administration of the railroad. In a mine railroad, this may not be an important cost center.

The major operating cost categories in a mine railroad in increasing order of importance are traffic control, power, locomotive repair, car maintenance, locomotive operation, and track maintenance. Each of these cost categories is both significant and identifiable. Costs records should also be broken down into the traditional operating cost categories of labor, supplies, power, and administrative and overhead costs for each category.

For example, data from an open pit mine (1984 costs) reveal that the rail haulage operating cost per ton hauled, calculated on the basis of nearly 40 million annual tons, was approximately \$0.50. The average one-way haul distance was 4.5 miles. The trains consisted of 12 cars, each 45 yd³ in capacity, hauled by a 2000 hp diesel electric locomotive. The

cost per ton-mile averaged \$0.12. Of the total cost of \$0.50 per ton, the labor costs were approximately 20¢/ton, the supplies, 15¢/ton, and general and administrative costs, the remaining 15¢/ton. Another breakdown of this \$0.50 was as follows: energy costs/ton, 15%; labor and supplies costs for maintenance of rolling stock, 15%; labor and supplies costs for maintenance of the way and structures, 33%; and cost of operating labor such as engineers, foreman, and supervisors, 37%.

An example will illustrate the application of the basic design formulas and costing procedure to the selection of a rail haulage system for an open pit mine. The example is contrived and simplified. It is presented only to outline the procedure.

Example 5: Given the following data, perform a job analysis for the rail haulage system, select the equipment, and calculate the ownership and operating costs.

General Data

ore reserve: 250 million tons
waste: 250 million tons
ultimate depth of pit: 800 ft
working days per year: 250
ore production per day: 30,000 tons
waste production per day: 30,000 tons
shift length: 8 hours (450 minutes working time)
number of shifts/day: 3

Average haul data for a trip

mining track: 1000 ft, 0%, average speed 5 mph
main line ramp: 26,640 ft, 3% against load, average curvature 10°, 800 ft lift, average speed 10 mph
rim of pit to dump: 8000 ft, 0%, average speed 25 mph for the first 6000 ft, and 5 mph for the last 2000 ft
speed of an empty train in good track: 35 mph;
maximum downhill speed is 20 mph.

Equipment Data

side dump cars: 40 yd³ or 80 ton capacity
empty weight: 40 tons
rolling resistance of cars: 5 lb/ton
locomotive rolling resistance: 5 lb/ton
curve resistance: 0.8 lb/ton per degree of curve
train size: 7 cars
loading time per car including spotting time: 5 min
dump time per car: 1 min
delay time per trip: 5 min
locomotive availability: 0.9
car availability: 0.83
cost of a locomotive: \$500,000
cost of a car: \$40,000

Seven miles of track grade construction work has to be done at a rate of \$50,000 per mile. The track construction cost on the working levels and dumps is \$120,000 per mile. It is estimated that 25 miles of track are to be laid on the dumps and the working levels. The mainline is a double-track (length = 26,640 ft + 6,000 ft = 32,640 ft), and construction costs average \$200,000 per mile. Additional investment in depreciable equipment (signals, maintenance machines, etc.) is \$2,000,000. It is proposed to use a 20-year useful life for all investment and 15% of the average annual investment for interest, taxes, and insurance. The cost of a gallon of fuel-oil is \$1.00, and each gallon will produce 11,500 ft-tons of gross work. Assume that fuel cost represents 20% of the operating costs.

Solution: The most severe condition for the locomotive haulage must be identified. The locomotive will be selected to haul the train up a 3% grade, 10° curve, at 10 mph.

Locomotive Selection:

weight of a loaded car = 40 + 80 = 120 tons
total weight of cars = 7 × 120 = 840 tons
let W = weight of locomotive, tons
total resistance to be overcome = tractive effort required = $W(5 + 20 \times 3 + 0.8 \times 10) + 840(5 + 20 \times 3 + 0.8 \times 10) = (73W + 61320)$ lb.

Assuming that at a running adhesion of 25% a speed of 10 mph is possible,

$$(0.25)(2000)(W) = 73W + 61320$$

$$W = 143.61 \text{ tons}$$

Choose a 144-ton locomotive for each train.

Cycle Time of a Train: The cycle time is the sum of the loading, travel loaded, dump, travel empty times, and delay time per trip.

loading time, 7 cars @ 5 min/car	= 35.00 min
travel loaded time:	
1000 ft @ 5 mph =	2.27 min
26,640 ft @ 10 mph =	30.27 min
6000 ft @ 25 mph =	2.73 min
2000 ft @ 5 mph =	4.55 min
dumping time @ 1 min per car	= 7.00 min
travel empty time:	
2000 ft @ 5 mph =	4.55 min
6000 ft @ 35 mph =	1.95 min
26,640 ft @ 20 mph =	15.14 min
1000 ft @ 5 mph =	2.27 min
delay time per trip	= 5.00 min
cycle time per trip	= 110.73 min

Number of Locomotives and Cars Required:

$$\text{number of trips per train} = \frac{450 \text{ min/shift}}{110.73 \text{ min}} = 4.06 \text{ trips}$$

Assume that a train will make four trips per shift.
production per train per shift = $4 \times 7 \times 80 = 2240$ tons

$$\text{number of trains required/shift} = \frac{20,000 \text{ tons/shift}}{2240}$$

$$= 8.93 \approx 9.$$

Since the locomotive availability is 0.9 and the car availability is 0.83,

$$\text{number of locomotives required} = \frac{9}{0.9} = 10.$$

$$\text{number of cars required} = \frac{9 \text{ trains} \times 7 \text{ cars/train}}{0.83} = 76$$

Fuel Consumption: The total work done in this haulage problem is calculated with the following assumptions:

1. the average lift for the load is 400 ft, since the final pit depth is given as 800 ft;
2. the average one-way haul to the dump is assumed to be 3 miles from the midpoint in the pit;
3. in the return trip, excepting for the first 8000 ft, the favorable gradient will power the trip; and
4. the rolling resistance for the train is assumed to be 10 lb/ton here.

The work done by a locomotive in a haul cycle is calculated as follows:

total load on a trip = weight locomotive + trailing loads

$$= 144 + 7 \times 120 = 984 \text{ tons}$$

$$\text{work done to lift the load, 400 ft} = 984 \times 400 \text{ ft-tons} \\ = 393,600 \text{ ft-tons}$$

work done to overcome the rolling resistance for 3 miles

$$= \frac{984 \times 3 \times 5280 \times 10}{2000} = 77,933 \text{ ft-tons}$$

work done to overcome the rolling resistance of 800 ft of track in the empty trip (weight of empty trip)

$$= 424 \text{ tons} = \frac{424 \times 8000 \times 10}{2000} = 16,960 \text{ ft-tons}$$

total work done in a trip = 488,493 ft-tons

fuel consumption for a trip

$$= \frac{488,493}{11,500} = 42.48 \text{ gallons}$$

fuel oil consumption per day (4 trips/locomotive, 9 locomotives/shift, 3 shifts/day)

$$= 42.48 \times 4 \times 9 \times 3 = 4588 \text{ gallons}$$

Cost Analysis: The cost analysis will be performed on a cost/hour and cost/ton basis.

$$\text{hourly production, tons} = \frac{\text{shift production}}{8 \text{ hr}} = \frac{20,000}{8}$$

$$= 2500 \text{ tons}$$

The capital costs are the sum of investments in track grade construction, track construction, locomotive, cars and other items.

track grade construction, 7 miles

$$@ 50,000/\text{mile} = \$ 350,000$$

track construction, 25 miles

$$@ 120,000/\text{mile} = \$ 3,000,000$$

double track construction (6.18 × 2)

$$\text{miles @ } 200,000/\text{mile} = \$ 2,473,000$$

locomotive cost, 10 @

$$\$500,000/\text{each} = \$ 5,000,000$$

cars costs, 76 @ \$40,000/each

$$= \$ 3,040,000$$

additional investment

$$(\text{depreciables only}) = \$ 2,000,000$$

$$\underline{\$15,863,000}$$

Cost of Ownership: This includes depreciation using the 20-year useful life, and the charges for interest, taxes, and insurance.

hours of work in 20 years assuming 8 hr/shift, 3 shifts/day, 5 days/week, 50 weeks/year = 120,000

$$\text{depreciation cost/hour} = \frac{\$15,863,000}{120,000} = \$132.19$$

interest, taxes and insurance/hour (assuming 6000 hour/

$$\text{year}) = \left(\frac{21}{2 \times 20} \right) (15,863,000) \left(\frac{15}{100} \right) \left(\frac{1}{6000} \right) \\ = \$208.20$$

total cost of ownership/hour = \$132.19 + \$208.20 = \$340.39 ≈ \$341.

$$\text{total cost of ownership/ton} = \frac{\$341}{2500} = \$0.14$$

If it is figured that taxes and insurance amount to 5%, then the \$0.14 can be broken down as follows: depreciation, \$0.05; taxes and insurance, \$0.03; and return (or interest) on average investment, \$0.06.

Operating Costs: The total operating costs in this example are calculated as a factor of the fuel-oil costs. Recapping the previously calculated figure, the fuel oil consumption per day was 4588 gallons.

$$\text{fuel-oil cost/day, 4588 @ } \$1/\text{gallon} = \$4588$$

$$\text{total operating cost/day} = \frac{\$4588}{0.20} = \$22,940$$

$$\text{operating cost/hour} = \frac{\$22,940}{24} = \$955.83 = \$956$$

$$\text{operating cost/ton} = \frac{\$956}{2500} = \$0.38$$

$$\text{total ownership and operating cost/hour} = \$341 + \$956 \\ = \$1297.00$$

ownership and operating costs/ton

$$= \frac{1297.00}{2500.00} = \$0.52$$

It may be necessary now to perform sensitivity analysis on such factors as the size of the trip, the grade of the track, the size of the cars, and the speed of the train. The simple costing procedure outlined here can be very useful for such an analysis. More detailed cost analysis incorporating investment tax credit, accelerated depreciation schedules, and financing considerations will be necessary in the final stages of the design and selection of the rail haulage system.

6.5.2. Trucks

RONALD M. HAYS

GENERAL APPLICABILITY

Trucks designed exclusively for off-highway use are the principal equipment for material transport in surface mines. In the mid-1930s, off-highway trucks were introduced to the mining industry; the first trucks of approximately 13.6-t (15-ton) capacity replaced highway trucks modified for mine haulage. By the mid-1950s, 22.7- to 27.2-t (25- to 30-ton) off-highway trucks were in common usage and trucks were available with 54.4-t (60-ton) capacity. In the late 1950s, single rear-axle trucks were introduced. During the 1960s and 1970s, bigger and better off-highway trucks were developed, with a 318-t (350-ton) capacity truck introduced in the mid-1970s.

Large and efficient off-highway trucks make possible the development of large low-grade ore and coal deposits. These deposits, with high stripping ratios and large quantities of both waste and ore or coal, are minable because of the economies of scale achieved with large off-highway trucks. Due to greater truck capacity and the resultant increased capital and operating costs, it has become increasingly important to analyze haulage requirements.

OFF-HIGHWAY TRUCK DESCRIPTIONS

Off-highway trucks can be classified into three main types: (1) conventional rear dump; (2) tractor-trailer, bottom, side, and rear dump; and (3) integral bottom dump. These main truck types are illustrated in Fig. 1.

The conventional rear dump is the dominant off-highway truck for surface mines. These trucks, with rigid frame and heavy duty dump body, are suitable for hauling almost all materials. The dump body mounted on the truck chassis is raised by an integrally mounted hydraulic hoist system. Trucks are powered by onboard diesel engines with either mechanical or electric wheel drives. Mechanical drives are available for trucks up to 118-t (130-ton) capacity while electric wheel drives are available in the 77.1- to 318-t (85- to 350-ton) capacity range.

Most conventional rear dump trucks have two axles with dual tires on the rear-drive axle. A two-axle truck is manufactured with both front and rear axle drive and dual tires on both axles. Some trucks are manufactured with three axles. These may have single or dual tires on the rear tandem axles and may be driven by one or both rear axles. Some small-capacity, three-axle trucks have articulated frames with front drive, rear drive, and tag axles, all with single tires.

Tractor-trailer units have a separate tractor as prime mover and a trailer connected by an articulated hitch. The tractors used for conventional rear dump trucks can be modified by removing the dump body and replacing it with a frame-mounted hitch. Tractors usually are powered by diesel engines and have mechanical drives; however, units with electric wheel drives are available. These units commonly have three axles: two on the tractor and one on the trailer. The rear-drive axle on the tractor and the trailer axle usually have dual tires.

Smaller tractor-trailer units up to 54.4-t (60-ton) capacity are available in the *overhung* or two-axle design. A scraper tractor with a single axle is used as the prime mover. This unit has greater maneuverability than the three-axle unit.

Tractor-trailer units are designed for rear, side, or bottom dump. Rear dump units commonly are used for ore or rock haulage, but also are available for lighter materials such as coal. These units usually have an integral hydraulic hoist system with collapsible wheel base. Thus, when the unit is dumped, the drive and trailing axles collapse closer together as the axle with brakes locked remains stationary.

Side dump tractor-trailer units are used for ore or rock haulage. These units may have either spillover dumping or drop-side dumping gates which carry material away from the tires. The dump body is raised by either an integral hydraulic hoist system or an external hoist or skyhook. Units with internal hydraulic hoist systems have a greater net vehicle weight (NVW), but can discharge anywhere. With an external hoist, units can be dumped only at hoist locations such as at a crusher. Units needing an external hoist usually are not as versatile because of dumping limitations.

Bottom dumps are the most common tractor-trailer units. These units are limited to free flowing material with trailers designed to haul specific materials such as alluvial material

Fig. 1. Large off-highway truck types.

or coal. Material is dumped through hydraulically operated doors designed for controlled opening and closing and for maximum ground clearance when open.

A wagon (dolly) or second trailer sometimes can be used with side and bottom dump tractor-trailer units. These wagons have two axles with dual tires usually on both axles.

Integral bottom dump trucks with rigid frame and large volumetric capacity are available in the 136- to 154-t (150- to 170-ton) capacity range for hauling coal. These trucks are powered by diesel engines with either mechanical or electric drives. These trucks have two axles with single tires on both front and rear; single tires on front and dual tires on rear; or dual tires on both front and rear. Dump doors are hydraulically operated. This truck design eliminates the hitch, gooseneck, and one axle, usually providing a high payload to gross vehicle weight (GVW).

Advantages and disadvantages of the three main truck types are presented in Table 1.

Drive Components

Engines used in off-highway trucks are either high speed (1800- to 2100-rpm) or low speed (900- to 1000-rpm) diesel engines. High-speed engines with outputs up to 1342 kW (1800 hp) are used for trucks with capacities up to 200 t (220 ton). Low-speed engines with outputs in the 1230- to 2461-kW (1650- to 3300-hp) range have been used for very large trucks in the 181- to 318-t (200- to 350-ton) capacity range.

High-speed diesel engines are either two-cycle or four-cycle engines. In recent years, manufacturers have improved engine reliability, durability, performance, and efficiency. Fuel efficiency has been substantially improved, principally by turbocharging and after-cooling, which increase air input to the engine. With turbocharging, engines also can be operated at higher altitudes without derating.

Low-speed diesel engines are two-cycle engines similar

Table 1. Large Off-Highway Truck Types: Advantages and Disadvantages

Conventional Rear Dump Truck

Advantages

Versatility, can haul wide variety of materials
Good gradeability because of favorable kilowatt (horsepower) to weight ratio (182 to 243 kg/kW) (300 to 400 lb/hp)
Good traction because of favorable weight distribution (65% or more of GVW on drive wheels)
Good performance under unfavorable road conditions
Good maneuverability because of short wheel base and small turning circle
Suitable for severe loading impact
Good for dumping into restricted hoppers and over banks
Provides maximum flexibility
Up to 318-t (350-ton) capacity.

Disadvantages

Poor for long-distance, high-velocity haul because of relatively high tire loading
Must stop, turn, and back up to dump load
Low-rated payload to GVW (rated payload 55 to 60% of GVW).

Tractor-Trailer Truck

Advantages

Versatility, can haul wide variety of materials depending on dump body type
Separate prime mover or tractor and trailer
Good for long-distance, high-velocity haul because of relatively low tire loading due to number of tires and to weight distribution
Good for dumping over hopper, building windrow, and dumping while moving
Favorable rated payload to GVW, especially for bottom dump coal haulers (rated payload 60 to 65% of GVW).

Disadvantages

Poor gradeability because of unfavorable kilowatt (horsepower) to weight ratio (274 to 365 kg/kW) (450 to 600 lb/hp)
Poor traction because of unfavorable weight distribution (35 to 45% of GVW on drive wheels)
Poor under unfavorable road conditions
Poor maneuverability because of large turning circle and long overall tractor and trailer length
Material must be free flowing if bottom dump
Not suitable for severe loading impact of bottom dump.

Integral Bottom Dump Truck

Advantages

Medium gradeability (228 to 335 kg/kW) (375 to 550 lb/hp)
Medium traction (50 to 65% of GVW on drive wheels)
Medium performance under unfavorable road conditions
Medium maneuverability
Good for long-distance haul because of favorable tire loading (not always the case)
Good for dumping over hopper
Favorable rated payload to GVW (rated payload 60 to 70% of GVW).

Disadvantages

Material must be free flowing
Not suitable for severe loading impact.

to those used on railroad locomotives. Low-speed engines have greater weight per kilowatt (horsepower) than high-speed engines, which is a major disadvantage in haulage equipment.

Engine power is transmitted to truck wheels either through mechanical or electric wheel drive. Mechanical drive consists of a transmission and final drive. The transmission usually is a fully automated power shift transmission consisting of torque converter, clutch-operated planetary gearing, and hydraulic controls with automatic direct drive lockup in all ranges. The transmission usually incorporates a hydraulic retarder so that the transmission can be utilized for braking. The recent development of transmissions for 746- to 1007-kW (1000- to 1350-hp) engines has extended mechanical drives to rear dump trucks in the 109- to 118-t (120- to 130-ton) capacity range. The final drive consists of a drive shaft, differential, full floating axle shafts, and planetary gears within drive wheels.

Electric wheel drive usually consists of a d-c generator or alternator, an exciter, d-c electric wheel motor mounted within the rim of each drive wheel, and planetary drive assembly within each drive wheel. In some 154-t (170-ton) capacity and larger rear dump trucks, electric motors are mounted inboard of the drive wheels. Electric wheel drive permits the engine to operate at constant speed with a smooth power loading. The electric motor also can serve as a retarder with the motor converting to a generator and energy dissipated as heat by air-cooled resistors.

With electric wheel drive, the onboard diesel engine can be assisted by an external overhead electric power source. Under trolley assist, electric power is collected from a fixed overhead conductor system and supplied directly to the wheel motors.

Brakes

Off-highway trucks commonly are equipped with four braking systems: retarder, service brakes, emergency brakes, and parking brakes. Primary braking is performed by the retarder. Mechanical drive trucks have an hydraulic retarder which is integral with the transmission or rear wheel service brakes. The hydraulic retarder integral with the transmission is positioned between the torque converter and planetary assembly. The retarder consists of a bladed rotor turned by the converter output shaft, a fixed casing or stator with vanes, and an oil circulation system. Retarding is accomplished by filling the casing with oil, which causes fluid resistance against rotor movement. The retarder integral with the rear wheel service brakes consists of oil-cooled, multiple disk brakes and an oil circulation and cooling system.

Electric wheel trucks are equipped with dynamic retarders which consist of the wheel motor, resistor grid, and grid cooling system. With dynamic retarding, wheel motors become generators and generated energy is dissipated as heat by the resistor grid.

Service brakes provide secondary braking and should be used only for truck stopping. Service brakes are either internal expanding shoe-drum or disk brakes. These brakes may be air, air-over-hydraulic, or all-hydraulic activated. Shoe-drum brakes are air-cooled while disk brakes may be either air- or oil-cooled. Trucks sometimes are equipped with shoe-drum brakes on the front axle and disk brakes on the rear axle.

Emergency brakes usually are integral with service brakes and can be applied manually or automatically upon loss of operating pressure in the service brake system.

Parking brakes on mechanical drives usually are an in-

ternal expanding shoe type on the transmission output shaft. For electric wheel drives, parking brakes may be integral with service brakes or mounted on the armature of the wheel motors.

Tires

Large truck tires are either bias ply or radial construction. The bias ply tire carcass is constructed of body plies that are 20 to 40 layers of rubber-cushioned nylon fabric with alternating plies of cord running from bead to bead and crossing the thread centerline at an approximate 30° angle (bias). In the tread area, body plies are overlaid with tread plies that improve carcass strength and protect the body plies. The radial tire carcass is constructed of a single heavy ply of steel cables running radially (90° bias angle) from bead to bead. The carcass is overlaid in the tread area by plies of steel cable or belts crossing the tread centerline at an angle with the angle reversed from the preceding belt. These belts provide the tire's radial strength and maintain the tire's shape under load. For both tires, the tread contacting the ground transmits truck weight to the ground and provides traction, flotation, cut resistance, and long wear.

Radial tires have the following advantages when compared with bias ply tires: (1) less heat generation and buildup; (2) lower fuel consumption; and (3) longer tread life. Heat generation due to tire flexing and internal friction among the various plies is reduced because of the single ply carcass. Radial tires also have less heat buildup because the steel ply conducts heat away from the tread and the thin carcass provides rapid heat dissipation. Heat buildup is especially important because the tire starts to weaken at about 93.3°C (200°F), making it more susceptible to impacts, cuts, and fatigue. At about 132.2°C (270°F), rubber *reversion* occurs and tire separation is imminent. Lower fuel consumption occurs because of less internal friction. Longer tread life results from less relative motion in the radial tire's footprint or *squirm*. However, the radial tire has the disadvantage of a thin sidewall, which makes the tire more susceptible to sidewall damage.

Tire size nomenclature designates tire cross section and rim diameter. As an example, a 30.00-51(46) tire is a bias ply standard base tire having an approximate width of 0.762 m (30 in.) between the outside of the sidewalls, a rim diameter of 1.275 m (51 in.), and a ply rating of 46. The same size radial tire is designated 30.00R51. Ply rating is an index of tire strength and does not necessarily mean the number of plies in the tire. The Tire and Rim Association (T&RA) has the following code identification for off-highway earth-mover tires:

- E-1 Rib
- E-2 Traction
- E-3 Rock
- E-4 Rock Deep Tread
- E-7 Flotation.

The E-3 and E-4 tires are most common for mine haulage with the E-4 tire having approximately 50% more tread than the E-3 tire. Radial tire manufacturers usually use different tire identification codes.

Tire load-carrying capacity, based on T&RA ratings, is the maximum load the tire should carry. This carrying capacity, at times, may be exceeded by 10 to 15% due to variations in truck loading without drastically reducing tire life. This carrying capacity increases as tire ply rating and inflation pressure increase. Optimum standard base tire pressures (cold) are 483 kPa (70 psi) for bias ply nylon tires and 586 kPa (85 psi) for radial tires. It is important to

maintain proper tire inflation because underinflation causes heat buildup and overinflation decreases impact and cut resistance.

Most off-highway tires have a tonne-kilometers per hour (t-km/h) (ton-miles per hour, tmph), rating, which is a tire work index related to heat buildup. The t-km/h (tmph) requirements are mean tire load times the hourly average velocity. Mean tire load is the average of the empty and loaded tire loads. Hourly average velocity is the maximum average velocity during any hour of operation. The t-km/h (tmph) requirement must not exceed the tire's t-km/h (tmph) rating to avoid excessive heat buildup.

In off-highway tire selection, factors to be considered in order of importance are: (1) t-km/hr (tmph) rating, (2) load-carrying capacity, and (3) tread thickness.

Dump Bodies

Rear dump bodies are available in several basic styles with the following most common:

- Transverse V-shaped, flat bottom floor;
- Transverse V-shaped, longitudinal V-shaped floor;
- Horizontal, flat bottom floor;
- Horizontal, longitudinal V-shaped floor.

For transverse V-shaped bodies, floor plates slope downward from rear to front, forming a transverse V with the front plate. For horizontal bodies, floor plate(s) are horizontal. A flat bottom floor has a flat floor plate. A longitudinal V-shaped floor has floor plates sloped downward from the side plates toward the center. All body types may have an upward sloped tail chute or ducktail at the rear for load retention. Bodies have either ribs or horizontal stiffeners to provide structural strength and rigidity.

Rear dump bodies usually are constructed of high strength alloy steels; however, lighter weight aluminum bodies also are available. Bodies heated by routing exhaust gases through structural supports prevents material from freezing to the body. Steel or rubber liners, plates, and bars may be installed to reduce wear. Top extensions (sideboards) and/or tailgates can be installed to increase volumetric capacity. However, added weight due to liners, sideboards, and tailgates decreases tonnage capacity of the truck.

Bottom dump trailers for tractor-trailer units are constructed in a variety of styles. Trailers for coal haulage usually are longer, narrower, and lower than rear dump bodies. Trailer bodies usually are constructed of high strength alloy steel, but of lighter gage than that used in rear dump bodies.

Rear dump and trailer bodies are designed for hauling specific materials resulting in a range of volumetric capacities, construction materials and methods, and body protection for the same tonnage capacity. However, the body always is designed to facilitate dumping and minimize material sticking and hangup and to reduce weight consistent with acceptable strength and wear.

Specifications

Off-highway truck manufacturers provide specifications of importance to the truck operator. These specifications frequently are determined in accordance with procedures established by the Society of Automotive Engineers (SAE) or other organizations.

Design payload or tonnage capacity specified is the weight the truck is designed to carry with manufacturer's standard equipment. If optional equipment substantially increases truck weight, the design payload must be reduced by a corresponding weight. Actual payload is the actual weight of material loaded, which depends on material density, loading

equipment, and operating conditions and varies from load to load. Truck performance and operating cost are based on actual payload rather than design payload. As a general rule, average actual payload should be as near as practical to and never exceed 110% of the design payload.

Volumetric capacity of the truck body is based on SAE struck and heaped 2:1 capacities. Neither of these capacities represents the volume of material that can be loaded into and hauled by the truck. Experience indicates that actual capacities are about 105 to 130% of SAE struck capacity with the highest percentage for the largest trucks with wide bodies and top extensions.

Engine kilowatt (horsepower) is based on rated brake and flywheel power. Rated brake power is engine kilowatt (horsepower) output at governed rpm and with manufacturer's approved fuel setting. Brake kilowatt (horsepower), torque, and fuel consumption curves usually conform to SAE standard J816b with conditions of 152.4-m (500-ft) altitude [0.7366 m (29.00 in.) Hg dry], 29.4°C (85°F) intake air temperature, and 0.965 cm (0.38 in.) Hg water vapor. Attached engine accessories usually include water pump, lubricating oil pump, fuel system, and air cleaner. Flywheel power is available engine kilowatt (horsepower) output or input power to the transmission for mechanical drives or to the generator or alternator for electric wheel drives. In addition to accessory power losses for brake kilowatt (horsepower), flywheel kilowatt (horsepower) usually includes losses for fan, air compressor, alternator, drive motor cooling fan, and hydraulic pump (no load). Actual engine kilowatt (horsepower) may vary $\pm 5\%$ from specified kilowatt (horsepower).

Net vehicle weight (NVW) is the weight of the empty truck with manufacturer's standard equipment. NVW may be specified as dry, wet, or operating weight. Wet or operating NVW includes lubricants, coolant, fuel, and operator. The NVW must be adjusted for installed optional equipment. NVW for a specific truck can be expected to vary $\pm 5\%$. Gross vehicle weight (GVW) is NVW plus actual payload. In manufacturer's specifications, GVW is NVW with standard equipment plus design payload.

Manufacturers specify truck weight distribution on each axle for an empty and loaded truck on level ground. However, weight distribution is not solely determined by the truck, but also by load placement and haulage road grade. Weight distribution is important in determining tire loading and traction.

Truck loading height is important in matching truck and loading equipment. There must be adequate clearance so that the loading bucket or dipper does not collide with the truck dump body top rail.

Clearance turning circle indicates distance required for the truck to make a 180° turn without backing. This determines truck maneuverability and can influence mine plan and truck spotting procedures.

Overall truck dimensions are important in the design of loading and dumping areas, haulage roads, and maintenance facilities. These dimensions also influence mine layout and loading equipment selection.

Special Equipment

Off-highway trucks can be equipped with a variety of special equipment to reduce maintenance, protect equipment, improve communications, and increase productivity. Maintenance can be reduced by special air cleaners, replaceable radiator core tubes, automatic lubrication systems, and automatic tire inflation systems. Instrumentation and recorders

such as the tachograph are available to monitor vital drive train data. Systems for truck protection include multifunction alarms, various interlocks, supplementary steering, ground level shutdown, and fire suppression. Special mirrors are available to improve operator visibility. Both voice and digital communication systems are available for truck monitoring and control. Truck productivity can be increased by fast fueling systems, cab climate control, and load indicators.

HAULAGE ROAD CONSIDERATIONS

Surface mine haulage roads must be located to minimize haulage cost while being consistent with other mine planning objectives. These roads must be constructed to insure efficient and safe truck travel.

Length

Haulage road length is a major consideration in truck selection, tire life, truck production, and haulage cost. Generally, road length should be minimized consistent with reasonable road grades.

Grade

Haulage road grades usually are determined as percent slope [(vertical rise/horizontal distance) \times 100]. Uphill grades or vertical rises are adverse or unfavorable grades, expressed as a positive (+) percent. Downhill grades or vertical falls are favorable grades, expressed as a negative (−) percent. Optimum grades for conventional rear dump trucks usually are 7 to 10%, but must be evaluated for specific trucks. For short distances, grades may be as high as 15%. Tractor-trailer units operate on lower grades than conventional rear dump trucks. Surface mining regulations for coal limit overall grades to a maximum of 10%.

Maximum unfavorable grades are limited by truck drive train and traction and ability to arrest the truck's backward movement. Maximum favorable grades are limited principally by truck retarding capability and emergency stopping distance. However, the ability to arrest a possible runaway truck also must be evaluated. Small trucks can descend steeper grades at higher speeds than larger trucks. For example, on a −10% grade, a loaded 45.5-t (50-ton) truck might descend at a maximum speed of 34 km/h (21 mph) while for a 90.7-t (100-ton) truck, the maximum speed should be reduced to 24 km/h (15 mph).

Sight Distance

Haulage roads must be designed with adequate sight distance for the operator to stop a truck traveling at operating speed before reaching a hazard. Sight distances are limited on vertical curve crests due to road surface and on horizontal curves due to berms, steep rock cuts, trees, structures, etc.

Construction

The haulage road must have a stable road base that adequately supports the heavy weight of off-highway trucks. In many mines, natural strata provide a satisfactory base. The road base must be overlaid by surface material such as crushed stone or gravel, coarse tailings, or stabilized earth. Surface material should have a high adhesion or traction coefficient under operating conditions.

Haulage road width for one- and two-lane travel should be 2.0 and 3.5 times truck width, respectively. The road must be sloped to the sides, usually 2.08 cm/m (0.25 in. per ft), for proper drainage. Drainage ditches must be placed along roadsides to control runoff from the road and surrounding area to avoid road damage.

At curves, road surface elevation must be raised from the inside to the outside of the curve (superelevation). This

superelevation is necessary to counteract the outward centrifugal force, reducing stress on tires, steering, and other vehicle components. Required superelevation is a function of friction factor, vehicle velocity, and curve radius. At sharp curves, it often is necessary to widen the road because of minimum turning circle and clearance.

Traffic signs should be used for posting velocity limits, stops, curve and intersection warnings, culvert crossings, controlling traffic, designating limited accesses, and indicating safety accesses. Berms must be placed parallel to the outside bank of elevated roads as a safety feature. Truck runaway escape lanes and/or collision berms are necessary to arrest runaway vehicles.

Resistance

Grade and rolling resistance provide resistance to truck movement. Grade resistance is the retarding or assisting force of gravity which is negative when traveling uphill and positive when traveling downhill. Grade resistance, the motion resistance due to the haulage road grade, is expressed as a percent grade or grade resistance factor. The grade resistance factor, *GRF*, is calculated by

$$GRF = 10 \text{ kg/t} \times \% \text{ grade}$$

or

$$GRF = 20 \text{ lb/ton} \times \% \text{ grade}$$

where 1% of vehicle weight is equivalent to 10 kg/t (20 lb per ton). The grade resistance, *GR*, is calculated by

$$GR = 10 \text{ kg/t} \times \text{vehicle weight in tonnes} \times \% \text{ grade}$$

or

$$GR = 20 \text{ lb/ton} \times \text{vehicle weight in tons} \times \% \text{ grade}$$

or

$$GR = GRF \times \text{vehicle weight in tonnes (tons)}$$

As an example, a truck weighing 136 078 kg (300,000 lb) traveling down a −8% grade has a grade resistance factor of −80 kg/t (−160 lb/ton) and a grade resistance of −10 886 kg (−24,000 lb).

These equations use percent grade or tangent of the grade angle which is satisfactory for low grades where tangent and sine of the grade angle are assumed equal. For steep grades, these equations should use sine of the grade angle.

Rolling resistance is motion resistance due to tire flexing under load, wheel bearing friction, tire penetration into the ground, and wind or air movement. Rolling resistance usually is expressed in kilogram per tonne (pound per ton) of vehicle weight, but also may be expressed as a percent of vehicle weight where 10 kg/t (20 lb/ton) equals 1%. Rolling resistance factor, *RRF*, in kilogram per tonne (pound per ton) is calculated by

$$RRF = R_f + R_p + (KAV^2/W)$$

where *R_f* is the resistance due to tire flexing and wheel bearing friction, commonly 15 kg/t (30 lb/ton) for radial tires and 20 kg/t (40 lb/ton) for bias ply tires;

R_p is the resistance per centimeter (inch) of tire penetration, 5.9 kg/t (12 lb/ton);

P is tire penetration, cm (in.);

K is the coefficient of air resistance, about 0.0066 SI (0.0035 English) for the off-highway truck;

A is the truck frontal area, m² (sq ft);

V is the air velocity, km/h (mph); and

W is the truck vehicle weight, tonne, (ton).

Resistance due to tire flexing and wheel-bearing friction is affected by tire type, tire inflation pressure, and wheel-

bearing design. Tire penetration is affected principally by haulage road surface and construction, but also by tire type, tread pattern, and tire inflation pressure. Air resistance is usually not considered in determining rolling resistance.

There is evidence that rolling resistance is affected by vehicle velocity with the rolling resistance factor, RRF , being approximated by

$$RRF = 1.075 RRF_n + 0.115V - 9.00 \quad (\text{SI})$$

or

$$RRF = 1.075 RRF_n + 0.50V - 18.00 \quad (\text{English})$$

where RRF_n is the nominal rolling resistance factor in kg/t (lb/ton) and V is the vehicle velocity in km/h (mph).

Table 2 presents typical or nominal rolling resistance factors for bias ply tires. For radial tires, these factors should be reduced by 5 kg/t (10 lb/ton). These factors normally are used independent of the vehicle velocity, but can also be used when considering vehicle velocity. Rolling resistance, RR , is calculated by

$$RR = RRF \times \text{vehicle weight in tonnes (tons)}$$

As an example, a truck weighing 136 078 kg (300,000 lb) with radial tires and 3.81-cm (1.5-in.) tire penetration, has a rolling resistance factor, RRF , of 37.5 kg/t (75 lb/ton) and a rolling resistance, RR , of 5103 kg (11,250 lb) assuming no wind resistance. With wind resistance resulting from a frontal area of 20.4 m² (220 sq ft) and a velocity of 32 km/h (20 mph), the RRF and RR are increased to 38.5 kg/t (77 lb/ton) and 5239 kg (11,550 lb), respectively. If vehicle velocity is considered and the vehicle has a velocity of 32 km/h (20 mph), RRF and RR are 36.3 kg/t (72.6 lb/ton) and 4940 kg (10,890 lb), respectively. However, if velocity is reduced to 16 km/h (10 mph), the RRF and RR decrease to 33.8 kg/t (67.6 lb/ton) and 4599 kg (10,140 lb), respectively.

Total resistance, TR , is the sum of grade and rolling resistance. Total resistance is the total resistance force to vehicle motion and usually is expressed as effective grade or percent of vehicle weight. As an example, consider a truck

weighing 136 078 kg (300,000 lb) traveling down a -8% grade with a rolling resistance factor of 37.5 kg/t (75 lb/ton) (equivalent to 3.75%). The total resistance, TR , is calculated by

$$TR = GR + RR = -10\,886 \text{ kg} + 5103 \text{ kg} = -5783 \text{ kg}$$

or

$$TR = GR + RR = -24,000 \text{ lb} + 11,250 \text{ lb} = -12,750 \text{ lb}$$

and the effective grade, EG , is

$$EG(\%) = GR(\%) + RR(\%) = -8\% + 3.75\% = -4.25\%$$

Traction

Traction is the usable driving force developed by the truck tire on the road surface. This usable driving force is limited by either drive train or road surface. The maximum force, F_M , which can be transferred from tire to road surface is a function of the coefficient of traction between tire and road surface, μ , and the normal force at the road surface, N . Thus, maximum force is

$$F_M = \mu N = \mu W \cos \theta$$

where W is weight on the tire and θ is grade angle. Coefficients of traction for various haul road surface materials are presented in Table 3.

As an example, consider a 77-t (85-ton) conventional rear dump truck traveling loaded up a 10% grade on a loose gravel haulage road with a rolling resistance factor of 100 kg/t (200 lb/ton) and a coefficient of traction of 0.35. As-

**Table 2. Typical Rolling Resistance Factors
Bias Ply Tires**

Haulage Road Surface	kg/t (lb/ton)	Equivalent % grade
Cement, asphalt, or soil cement without tire penetration	20 (40)	2
Hard-packed gravel, cinders, or crushed rock	30 (60)	3
Firm packed earth or light surfacing	32.5 (65)	3.25
Moderately packed gravel, cinders, or crushed rock	50 (100)	5
Rutted or unmaintained earth	75 (150)	7.5
Loose sand and gravel	100 (200)	10
Soft, muddy, rutted, and unmaintained material	100-200 (200-400)	10-20

Table 3. Coefficient of Traction for Various Haulage Road Surface

Haulage Road Surface	Coefficient of Traction	
	Rubber Tires	Tracks
Concrete, new	0.80-1.00	0.45
Concrete, old	0.60-0.80	
Concrete, wet	0.45-0.80	
Asphalt, new	0.80-1.00	0.50
Asphalt, old	0.60-0.80	
Asphalt, wet	0.30-0.80	
Gravel, packed and oiled	0.55-0.85	0.55
Gravel, loose	0.35-0.70	
Gravel, wet	0.35-0.80	
Rock, crushed	0.55-0.75	0.90
Rock, wet	0.55-0.75

Ice, wet	0.05-0.10	0.12
Coal, stockpiled	0.45	

suming the GVW is 136 078 kg (300,000 lb), the resistance to movement or required rimpull is 27 216 kg (60,000 lb). Assuming weight on rear drive tires is 90 718 kg (200,000 lb), the maximum force that can be transferred from drive tires to road surface is 31 751 kg (70,000 lb). Since maximum rimpull and force that can be transferred are greater than the resistance of 27 216 kg (60,000 lb), the truck can move up this grade. However, if the truck is empty with only 31 751 kg (70,000 lb) on the rear drive tires, resistance to movement is reduced to 11 793 kg (26,000 lb). This is greater than the 11 113 kg (24,500 lb) that can be transferred from drive tires to road. Thus, the empty truck cannot travel up this grade without improving the road surface to reduce the rolling resistance factor.

Velocity Limits

Truck velocity limits are necessary on favorable downhill grades, curves, loading and dumping areas, and congested traffic areas. On favorable grades, truck velocity depends primarily on retarding capability and emergency stopping distance. On curves, truck velocity must be consistent with the road superelevation. In loading and dumping areas, truck velocity usually is limited to 13 to 16 km/h (8 to 10 mph), depending on ground conditions and congestion.

Maintenance

Good haulage road maintenance is essential to avoid costly truck operating and maintenance problems. A motor grader should be used continually to fill and smooth potholes, ruts, depressions, and bumps; maintain cross slopes; and remove spillage, ice and snow. Haulage road dust should be controlled by watering and/or chemicals. However, excessive water should be avoided.

PERFORMANCE

The truck's performance characteristics determine its ability to haul material effectively under specific haulage conditions. Performance is determined by the interaction between truck and haulage environment with certain trucks designed to haul most effectively under specific haulage con-

ditions. Of particular importance are truck weight and its distribution, drive train, retarding and braking systems, and tires. For maximum utilization and availability, it is also important that the truck be designed and manufactured for reliability, maintainability, and driver acceptance. Specific haulage conditions affecting performance are haulage road distances, grades, construction, and maintenance; altitude and temperature; and operating procedures and practices.

Horsepower Utilization

The performance curve or rimpull vs. velocity curve characterizes drive train performance when the truck is operating against positive resistance to movement. Figs. 2 and 3 present typical performance curves for mechanical and electric wheel drive trucks, respectively. The vertical axis is the rimpull or force the drive train can produce at the drive tires-ground contact. The horizontal axis is the truck velocity. The performance chart shows the maximum rimpull the drive train can provide when the truck is traveling at the specified velocity. Because the truck must overcome resistance to movement, the performance chart indicates the maximum truck velocity when resistance force is equal to truck rimpull force.

The performance curve for the mechanical drive truck (Fig. 2) has a series of discontinuities representing gear changes. The lower portions of the curve occur when the power is transmitted by the torque converter; the upper portions occur when the transmission is locked up and slippage is eliminated. The performance chart for the electric wheel drive (Fig. 3) has three discontinuities due to voltage and current limitations and electric field shunting. At low velocities, rimpull is limited by maximum current. At high velocity, velocity is limited by maximum voltage.

As an example, consider a 109-t (120-ton) capacity truck with the performance curve shown in Fig. 2 and an assumed resistance to movement of 12 700 kg (28,000 lb). With this resistance to movement at equilibrium with the rimpull, the truck can maintain a velocity of 21 km/h (13 mph). If resistance to movement increases, the truck would decelerate until equilibrium between the higher resistance to movement

Fig. 2. Performance and retarding curves for mechanical drive trucks.

Fig. 3. Performance and retarding curves for electric wheel drive trucks.

and rimpull is attained at a lower speed. If resistance to movement decreases, the truck could accelerate until attaining equilibrium.

The rim kilowatt (horsepower), kW_R (hp_R), or power the drive train can deliver at the drive tires-ground contact is calculated by

$$kW_R = \frac{\text{rimpull (kg)} \times \text{velocity (km/h)}}{367.1}$$

or

$$hp_R = \frac{\text{rimpull (lb)} \times \text{velocity (mph)}}{375}$$

Drive train efficiency is the portion of engine kilowatt (horsepower) available as rim kilowatt (horsepower). Drive train efficiency usually is based on engine flywheel kilowatt (horsepower).

It is important that the drive train operate at a relatively high efficiency level, usually about 80 to 90%. Drive train energy losses occur as heat which must be dissipated to the environment. Mechanical drives are designed with heat exchangers connected to the cooling system to cool the torque converter, the principal heat source. Cooling capacity usually is adequate to dissipate 30% of the flywheel kilowatt (horsepower) on a continuous basis under normal ambient temperature and humidity. Thus, continuously operating the drive train at efficiencies below 70% efficiency may cause overheating and eventual component failure. Electric wheel motors are provided with forced air ventilation for cooling. Heat generation exceeding cooling capacity can cause deterioration of insulation and eventual motor damage. If the truck will be operated in the low efficiency range or under extreme ambient conditions, the manufacturer should be consulted to determine truck suitability and possible additional cooling capacity.

The manufacturer's performance curve must be adjusted for altitude, temperature, and tire size if different from those specified. As altitude increases or temperature rises, air density decreases, adversely affecting engine power output. En-

gine manufacturers provide information on performance derating for each specific engine. Naturally aspirated engines may have to be derated at altitudes greater than 304.8 m (1000 ft) above sea level while turbocharged and after-cooled engines may not need to be derated until altitudes of 1524 m (5000 ft) or more above sea level. Adjusted drive train performance can be obtained by derating the rimpull on the manufacturer's performance curve. As an example, consider an engine that is derated to 93% of rated kilowatt (horsepower) at an elevation of 3048 m (10,000 ft). Adjusted rimpull then is 0.93 times the rimpull specified by the manufacturer's performance curve.

The manufacturer's performance curve is for a specified tire size. Since rimpull is wheel or hub torque divided by effective loaded tire radius, and velocity is wheel rpm divided by tire revolutions per kilometer (mile), both rimpull and velocity must be adjusted for tire size. Both adjustments use tire revolutions per kilometer (mile) which is proportional to effective tire loaded radius. Rimpull, F , velocity, V , and tire revolutions per kilometer (mile), R , are adjusted as follows:

$$F_2 = F_1 \times (R_2/R_1)$$

and

$$V_2 = V_1 \times (R_1/R_2)$$

where i is 1 for manufacturer's performance curve and i is 2 for adjusted values with optional tires. This same approach also may be used to adjust the performance curve for different drive train gear ratios.

The rimpull specified by the manufacturer's performance curve may be derated to penalize the engine for extended operating hours or poor mechanical condition. However, operating experience indicates that the performance of a well maintained and properly adjusted engine does not substantially deteriorate during normal engine life.

For rimpull to be a usable driving force, this force must be transmitted from the drive tires to the road surface causing truck movement. Transfer of rimpull to the road surface may

be limited because of poor road surface or weight on drive tires (see the earlier section on *Traction*). Thus, usable driving force (usable rimpull or traction) may be limited by either rimpull or maximum force that can be transferred from the tire to road surface, whichever is less.

Retarding

When the truck is operating with negative resistance to movement, retarding capabilities of the truck's drive train and related components are characterized by the retarding curve. Figs. 2 and 3 present typical retarding curves for mechanical and electric wheel drive trucks, respectively. The vertical axis is the retarding or rimpull force resisting movement at the drive tires-ground contact. The horizontal axis is truck velocity. The retarding curve and performance curve are similar except the rimpull on the retarding chart is negative, a force resisting movement.

The retarding chart shows retarding force, excluding service brakes, available when the truck is traveling at a specific velocity. The retarding curve for the mechanical drive truck (Fig. 2) has a series of discontinuities related to various transmission gears. For electric wheel drive (Fig. 3), step extended range retardation provides discontinuities in lower velocity ranges.

Accepted practice is to operate the truck at velocities lower than indicated by manufacturer's retarding curve because the curve is the maximum retarding capability. For mechanical drives, the truck usually is operated at least one gear lower than indicated by the retarding curve. As an example, consider a 109-t (120-ton) truck with the retarding curve in Fig. 2. If the required retarding force is 12 700 kg (28,000 lb), the truck could be operated at 40 km/h (25 mph) in fifth gear. However, a velocity of 30 km/h (19 mph) in fourth gear is preferred for safe operation. For both mechanical and electric wheel drives, there is a time lag between the operator activating the retarder control and activation of the retarding system. During this time lag, the truck may accelerate and gain velocity on a downhill or favorable grade. Thus, retarder control must be activated at a velocity lower than indicated by the retarding curve.

The manufacturer's retarding curve is for a specified tire size. If the tire size differs from the size specified, both retarding force and velocity of the retarding curve must be adjusted in the same manner as rimpull and velocity were adjusted for the performance curve.

Retarding systems are not capable of stopping a truck. Thus, service brakes are needed to bring the truck to a complete stop.

Gradeability

Gradeability is the ability of a truck to negotiate a given haulage road, taking into consideration total resistance to movement, including grade and rolling resistance (see the section on *Resistance*). Travel time required for a truck to travel from one location to another is based on the truck performance curve, retarder curve, net vehicle weight (NVW), and the actual payload; haulage road grade and rolling resistance; velocity limits and other operating constraints; and operator performance.

Computer simulation programs are available for calculating theoretical travel time. These programs provide quick, accurate, and inexpensive means for calculating travel time, permitting extensive analysis and comparison of trucks, haulage road designs, and operating practices. These computer programs use a variety of methods and procedures, but estimated travel time for most programs is within acceptable

limits. These programs require that the haulage road profile be divided in segments with each segment having a unique length, grade, rolling resistance, and velocity limitations. An incremental analysis (time, distance, or velocity) is used to simulate truck travel.

Acceleration, rotating mass, shifting and lag times, resistance to movement, deceleration, and braking may be treated differently in the programs. Care must be taken to insure that acceleration and deceleration rates are within ranges acceptable to truck operators. Acceptable maximum acceleration and deceleration rates usually are between 4.8 and 9.7 km/h/s (3 and 6 mph per sec) and 3.2 and 6.4 km/h/s (2 and 4 mph per sec), respectively.

Theoretical travel time then must be adjusted to actual travel time based on operator performance. For short haul distances of 305 to 610 m (1000 to 2000 ft), a truck may operate at 80 to 85% of theoretical performance. For long hauls of 2.4 km (1.5 mile) or more, 95% of theoretical performance may be attained. As an example, actual truck travel time would be 3.0 min for a 610-m (2000-ft) haul with a 2.4-min theoretical travel time operating at 80% of theoretical performance ($2.4 \text{ min}/0.80 = 3.0 \text{ min}$).

Trolley Assist

Trolley assist for electric wheel drive trucks uses an overhead electric power source to supply electric power for electric wheel motors. This external electric power supplements the power available from the onboard diesel engine and d-c generator or alternator.

An electric trolley assist system consists of an overhead power source along the haul road and a truck-mounted power collection and auxiliary control equipment. The overhead power source is primarily an a-c power distribution system feeding a rectified d-c power distribution system consisting of fixed wires or bus bars suspended above the haulage road. Transformer-rectifier substations step down and convert commercially available a-c power to d-c power. Substation size and location depend on specific mine requirements: truck traffic density, length of trolley haul, truck specific drive system, and frequency of overhead equipment relocation.

The fixed overhead dc transmission system can use either wire or bus bars. Wire has the advantage of lower initial cost, but the disadvantages of lower current and wire sag. Electric current requirements may require larger wire and multiple feeder points. Sag may be corrected by closer pole spacings, tensioning devices, and full catenary support. Bus bars are advantageous at mines with steep grades and high traffic density. Bus bars may have lower overall cost because of greater flexibility to meet changing traffic densities, less feeder points, and easier repair of sectionized bus bars.

Electric power is collected from the overhead d-c transmission system by either a trolley pole or pantograph mounted on the truck. The trolley pole can be used with overhead wire or bus bars, but the pantograph can be used only with overhead wire. The trolley pole can accommodate terrain changes and reasonable steering variation, but requires an entry guide assembly to engage the trolley pole to the overhead wire or bus bar. The pantograph can engage the overhead wire at any point along the wire, but has the disadvantages of being a larger structure and decreasing operator visibility.

Trolley electronic controls, logic relays, and power contractors are truck-mounted. Existing retarding resistors are also used as trolley accelerating step resistors. Protective features include ground leakage current detection, grid resistor protection, wheel motor overcurrent protection, line

voltage protection, interlocking protection, and deadman control. Power collection and control equipment can be installed in new or in-service electric wheel drive trucks.

A trolley assist equipped electric wheel drive truck can be operated in either *diesel* or *trolley* operating mode. In *diesel* mode, the truck is powered by the onboard diesel engine. In *trolley* mode, the truck is powered principally by the external electric power source with the onboard diesel engine providing power for grid resistor and motor cooling air and all engine driven auxiliary systems. The truck operator can override automatic trolley controls to stop on grade, adjust speed, or switch to diesel operating mode.

Major advantages of using trolley assist are reduced diesel fuel consumption, increased productivity, improved deep pit capability, and decreased diesel engine maintenance. Major disadvantages are increased onboard truck equipment, electrical maintenance, tire wear, and electric wheel motor maintenance.

Trolley assist is most applicable at mines with high cost and limited availability of diesel fuel and with low cost and abundant electric energy. At these mines, lower cost commercial electric power can replace high cost diesel fuel. Increased productivity occurs because trolley assisted trucks usually can achieve higher velocities on grades. Power output of the truck diesel engine generally is less than the power output of the electric wheel motors. Thus, the trolley operating mode permits a truck to operate at the maximum power output of the electric wheel motors rather than the lower power output of the diesel engine.

Improved deep pit capability occurs because electric wheel motors are more efficient with trolley assists, reducing heat buildup on long grades. Diesel engine maintenance is reduced because of reduced engine duty cycle, but electric wheel motor maintenance increases because of increased motor output. Tire wear will increase because of increased rim-pull and higher average speeds. However, the cost associated with increased wheel motor maintenance and tire wear may be offset by increased productivity.

Automatic Truck Control (ATC)

The ATC system is an electronic system that controls the haulage truck fleet by providing automatic control of all vehicle functions normally accomplished by the operator of each truck. Functions controlled include truck steering, direction, acceleration, velocity, retarding, braking, stopping, separation, dumping, etc. The system also monitors oil pressure, water temperature, tire pressure, and other critical truck functions.

The system consists of wayside and onboard control equipment. Wayside equipment consists of a guide wire buried in the haulage road in the truck's path, block control units, and a central controller which provides predetermined signals. Onboard antennas receive commands from wayside equipment and then equipment controls the truck's functions. Onboard sensors monitor critical truck functions and transmit the data to the wayside equipment. In the event of malfunction, onboard equipment brings the truck to a safe stop. For loading and dumping, the truck may be operated manually or by radio remote control.

ATC systems have the potential advantages of reducing operating labor, increasing truck and shovel utilization, decreasing truck maintenance and downtime, decreasing truck fuel consumption, assuring proper truck loading and dumping destinations, and safer operating conditions.

TRUCK CYCLE TIME

Truck cycle time is time required for the truck to complete a single cycle including spot and load, haul loaded, turn and dump, return empty, wait, and delays. The productivity of an operating truck is dependent on the average actual payload and average cycle time. Matching of loading equipment (front end loader, shovel, etc.) and truck are important to ensure appropriate payloads and loading times. The method of spotting and loading trucks influences spot and load times. Haulage road layout and design, including length, grade, rolling resistance, curves, and velocity limits affect travel times. Travel times also will be affected by driver skill and attitude, road maintenance, and truck maintenance. Velocity or travel time for the slowest truck in the fleet tends to set the fleet pattern, especially with a no overtaking policy. Space and ground conditions, as well as the necessary support equipment, influence turn and dump times. Climate and weather conditions can result in poor equipment performance and operating delays. Truck haulage, with many operating trucks, is capital intensive, requiring good engineering and supervision to ensure maximum productivity from available equipment.

Large-scale truck haulage systems are complex operations requiring synchronization of loading and hauling equipment. To analyze this complex system, it is necessary to break down and examine various detailed elements in the truck cycle time. This analysis is based on time studies and related operating experience. Using mine planning information to establish mining sequence and haulage road layout, truck cycle times and the resultant system production can be analyzed.

Complex haulage systems usually are analyzed by computerized simulation. Simulation may be either simple deterministic or sophisticated stochastic simulation. Deterministic simulation uses constant values for system parameters such as actual payload and parameters related to truck cycle time. Stochastic simulation uses probabilistic techniques, such as the Monte Carlo method, to vary values for system parameters. Stochastic simulation requires extensive field data on parameter variability. These data can best be collected with real time monitoring systems such as those developed to provide information for computerized truck dispatching systems. Data from previous stochastic simulation also may be incorporated into deterministic simulation, so that deterministic simulation may include probabilistic effects for certain haulage situations.

Spot and Load

Spot time is the time needed for the truck to maneuver into position for loading. Load time is the time required for the loading machine to make the required number of passes to load the truck. These times may interact because the loading machine may perform parts of its work cycle while the truck is being spotted.

Combined spot and load time depends on space and ground conditions, loading equipment, loading method, rock fragmentation, and match of loading equipment and trucks. Trucks can be loaded with a variety of equipment: wheeled or tracked front-end loaders, hydraulic or cable shovels, backhoes, draglines, bucket-wheel excavators and conveyor belt loaders, and hoppers or bins with controlled gates.

Wheeled front-end loaders are commonly used to load trucks from blasted rock faces and stockpiles. The loader is highly mobile and maneuverable, but requires good ground conditions because of high ground-bearing pressures at the

tire-ground contact. Digging forces of the front-end loader generally are less than for cable or hydraulic shovels. Thus, a loader may require a dozer to push material to the loader, breaking fragment interlocking of hard digging material. The loader and truck must be properly matched, with the loader having adequate bucket capacity and reach.

Three principal loading methods using front-end loaders are:

1) Single truck loading where the truck is spotted by backing and stopping near the face and loaded from one side of the truck by a single loader.

2) Tandem truck loading where the truck is spotted by backing toward and stopping near the face and loaded from both sides of the truck by two loaders, one on each side of the truck.

3) Drive-by loading where the truck drives forward and stops near the loader and is loaded from one side of the truck by a single loader (common for tractor-trailer units).

Other more complex methods have been developed, such as staggered tandem and chain loading. The loading method depends on bench slope, available space, production requirements, ore grading constraints, and operator experience.

Spot time for large rear dump trucks usually is between 0.40 and 0.70 min. Spot time for tractor-trailer units may range from 0.15 to 1.00 min., depending on loading method and the need for backing.

Load time is the time needed for the loader to load the truck. Load time depends on the number of passes required to load the truck and the loader work cycle time. Number of passes, N_p , can be calculated by

$$N_p = \frac{C_t}{C_l \times F_s \times F_r \times \rho}$$

where C_t is the truck capacity, (ton); C_l is the loader rated capacity, m^3 (cu yd); F_r is the loader bucket fill factor, decimal; F_s is the material swell factor, decimal; and ρ is the material bank bulk density, t/m^3 (st per cu yd). Bucket fill factor is the ratio of volume of loose material in the bucket to rated volume capacity of the bucket. Swell factor is the ratio of the material's loose to bank bulk densities.

Truck capacity usually is based on truck design payload, but, in some cases, may be limited by truck volumetric capacity. As a general rule, the number of passes should be an integer so that the truck average actual payload does not exceed design payload. The most economical number of passes usually is four to six for conventional rear dump trucks. Less than four passes usually requires a very large loader with excessive capital cost while more than six passes increases truck requirements because of increased loading time.

Front-end loader work cycle time is the time required for a loader to make one complete cycle of dig from bank, retreat from face, advance to truck, dump bucket, retreat from truck, advance to face, and position at face. Table 4 presents nominal work cycle times for various capacity front-end loaders. These nominal times are based on the loader being properly operated and having adequate digging forces and appropriate bucket for the materials being excavated. Thus, it may be necessary to adjust these nominal times based on the specific loader, operator experience, material characteristics, and operating conditions. These nominal times also may increase because of excessive loader travel and/or maneuver time due to poor truck spotting. Long or variable work cycle times indicate inadequate loader capabilities or poor operating procedures. In some cases, inadequate loader digging forces can be overcome by blasting for

Table 4. Front-End Loader Work Cycle Times

Bucket Capacity m^3 (cu yd)	Nominal Minutes
0-3.1 (0-4)	0.45
3.1-5.4 (4-7)	0.50
5.4-7.6 (7-10)	0.55
7.6-15.3 (10-20)	0.60

better fragmentation and/or by a dozer pushing to the loader.

If spot time is less than the loader work cycle time, combined spot and load time, t_{tl} , in minutes can be calculated by

$$t_{tl} = N_p t_{lc}$$

where t_{lc} is the loader work cycle time in minutes. If the spot time is greater than the loader work cycle time, combined spot and load time, t_{tl} , can be calculated by

$$t_{tl} = (N_p - 1) t_{lc} + t_s = N_p t_{lc} + t_s - t_{lc}$$

where t_s is the truck spot time in minutes.

Hydraulic and cable shovels commonly are used to excavate and load harder digging materials with cable shovels generating the greatest digging forces. Because shovels are mounted on a crawler track assembly, these machines can be designed to operate with low ground bearing pressures. Poor shovel mobility usually requires that a dozer perform cleanup around the shovel.

The four principal loading methods using shovels are:

1) Single backup loading where the truck is spotted by backing on the operator side of shovel and stopping near the face so that the shovel, with tracks aligned toward the face, has a maximum swing of 90° .

2) Double backup loading where trucks are spotted and loaded on both sides of the shovel by trucks alternating backing and stopping near the face on the operator side and then on the opposite side of the shovel with shovel tracks aligned toward the face and a maximum swing not exceeding 90° .

3) Drive-by loading where the shovel tracks are oriented parallel with the face and the truck drives forward and stops directly opposite the shovel, with a maximum shovel swing not exceeding 180° .

4) Modified drive-by loading where the shovel tracks are aligned parallel with the face and the truck drives forward under the shovel swing path with the dipper dumped before the truck stops, then the truck is stopped and spotted by backing and stopping near the face, with a maximum shovel swing angle of 120° .

For all loading methods, the trucks should be spotted so that the dipper swing path is along the major axis of the truck body, presenting a maximum target area and center of payload. The loading method selected depends on bench shape, available space, production requirements, ore grading constraints, and operator experience.

Spot times for trucks at shovels are similar to spot times for front-end loaders and depend on the loading method. As with front-end loaders, load times for shovels depend on the number of passes and shovel work cycle time. For shovels, the number of passes may be calculated in the same manner as described for front-end loaders, with the most economical number of passes usually ranging from three to six for con-

ventional rear dump trucks. However, the number of passes sometimes may be calculated using dipper factor rather than dipper fill and material swell factors. The dipper factor is the ratio of volume of material in the dipper based on bank material or volume to rated volume capacity of the dipper.

These factors are related by

$$F_d = F_f \times F_s$$

where F_d is the shovel dipper factor, decimal; F_f is the shovel dipper fill factor, decimal; and F_s is the material swell factor, decimal.

The shovel work cycle time is the time required for the shovel to make one complete cycle of dig from and clear the bank, swing to dump position, dump dipper, swing back to bank lowering dipper, and position to dig. Table 5 presents cable shovel nominal work cycle times based on hard digging material and a 90° swing. These nominal times should be decreased 0.08 min. for easy digging and 0.04 min. for medium digging conditions and increased 0.04 min. for very hard digging conditions. These nominal times also must be adjusted by increasing or decreasing work cycle time 0.01 min. for each 5° increase or decrease in average swing.

The cable shovel nominal work cycle times in Table 5 are based on modern electric mining shovels with complete a-c drive systems using sophisticated electronic controls. The work cycle times will vary depending on specific drive system and digging conditions. Substantially longer times may occur for older shovels having Ward Leonard drive systems. For hydraulic shovels, nominal work cycle times can be reduced approximately 0.05 min. In addition to drive system and digging conditions, shovel work cycle time also may be influenced by shovel design, operator experience, bank height, and other operating conditions.

The combined spot and load time for shovels is calculated in the same manner as previously described for front-end loaders.

Travel

Travel time includes time to haul loaded to the the dump point and return empty to the loading equipment. Travel time depends on truck gradability, haulage road, operating constraints, and operator performance and can be calculated best by computer simulation programs (see the section on *Gradability*). Operating constraints such as velocity limits are required for downhill or favorable grades, curves, narrow bridges and tunnels, cross traffic areas, and congested traffic areas. Velocity limits may be further restricted because of adverse weather such as snow, ice, fog, and rain. Velocity limits also may be required to keep truck tires below their

tonne-kilometers per hour (t-km/h) (ton-miles per hour, tmph) rating. The velocity of the slowest truck in the fleet may restrict velocity of other trucks. Good haulage road maintenance will reduce travel time.

Turn and Dump

Turn and dump time depends on truck type and size, material characteristics, dump arrangements, space available, ground conditions, and operating practices. A rear dump truck enters the dump area, turns, back up, stops, raises body to dump payload, and lowers body. The time to hoist and lower the body of rear dump trucks ranges from about 0.30 to 0.70 min; time generally increases with payload. A bottom dump tractor-trailer unit drives forward through or over the dump area, sometimes dumping without even stopping.

Nominal turn and dump times are 1.00 min. for conventional rear dump trucks and 0.50 min. for tractor-trailer units. Nonfree-flowing, sticky, and/or frozen material may substantially increase these times and reduce actual payload. These nominal times may be less when dumping into a hopper and greater when dumping on a waste dump. At waste dumps, auxiliary equipment such as a dozer or grader usually is required for proper dump construction. While space usually is not limited on waste dumps and stockpiles, poor ground conditions may exist. Operating practices that maintain the dump area and minimize traffic congestion and safety hazards will decrease turn and dump times.

Wait

Truck wait time occurs when the truck must wait to be loaded or to dump because of nonsynchronization in the haulage system. Wait time occurs because of the following:

- 1) Over-trucking exists when the number of trucks in the system exceeds loading and/or dumping capabilities.
- 2) Bunching results when the spacing between trucks is reduced due to mixing faster and slower trucks or fleet start-up.
- 3) Mismatching of equipment exists when the system has variable size equipment with variable performance characteristics (i.e., small and large trucks in the same fleet) resulting in variable truck cycle times.
- 4) Weather conditions such as rain or ice which result in variable truck cycle times.
- 5) Operator performance causing variations in truck cycle times due to human participation.

Wait times can be reduced by improving truck allocation and supervision and by dispatching systems.

Wait time due to variable truck cycle times can be estimated based on the coefficient of variation of cycle times. Coefficient of variation, C_v , is calculated by

$$C_v = \frac{\sigma}{\bar{x}}$$

where σ is the standard deviation and \bar{x} the mean. The coefficient of variation normally is from 0.10 to 0.20 for truck cycle times. A low coefficient of variation indicates a well synchronized system with a minimum of wait time.

Methods for estimating wait time include field studies, efficiency factors, and simulation. If practical, wait time should be estimated by simulation based on field studies rather than simple job efficiency factors.

Delays

Operational delays that reduce production can be classified as fixed or variable delays. Fixed delays are predictable

Table 5. Shovel Work Cycle Times Hard Digging Conditions

Dipper Capacity m ³ (cu yd)	Nominal Minutes*
4.6(6)	0.47
6.9(9)	0.48
9.2(12)	0.49
11.5(15)	0.50
15.3(20)	0.52
19.1(25)	0.53

* Based on 90° swing.

as to time of occurrence and duration such as shift change, equipment inspection, breaks, refueling, blasting, etc. Fixed delays usually are not considered in truck cycle time. Variable delays are not predictable as to time of occurrence and duration. Variable delays include delays for haulage road maintenance, loading area cleanup, driver relief stop, loading oversized rock, etc., and are considered in the truck cycle time. Unscheduled mechanical delays are variable delays, but these are not considered in the truck cycle time.

Variable delays causing variations in the truck cycle time will result in increased truck wait time. These delays and associated wait time can be estimated by the same methods used for estimating wait time.

Total Cycle Time

Total truck cycle time is the summation of spot and load, haul loaded, turn and dump, haul empty, wait, and delay times. Total cycle time usually is expressed as an average time for specific loading equipment and trucks operating on a specific haulage road.

PRODUCTION AND FLEET REQUIREMENTS

Truck production and fleet requirements are affected by many factors: mine plan, haulage roads, mine production requirements, loading equipment, truck performance and cycle time, operating methods and practices, matching of loading equipment and trucks, and equipment availability and utilization. Methods used to estimate and evaluate truck production and fleet requirements vary from simple rules of thumb to complex computerized simulation.

Matching Trucks and Loading Equipment

Based on truck cycle and spot and load times, trucks and loading equipment must be matched to avoid excessive over- or under-trucking the loader or shovel. The theoretical number of trucks that can service a loader or shovel, N_T , can be derived by

$$N_T = \frac{t_{tc}}{t_{tl}}$$

where t_{tc} is the total theoretical truck cycle time (no wait time) in minutes and t_{tl} is the truck spot and load time in minutes. In calculating the theoretical number of trucks, N_T , the truck wait time, must be excluded from the truck cycle time. For loading methods where an arriving truck is spotted while another truck is loaded, truck spot and load time is replaced by loader or shovel loading time.

If the number of trucks is less than N_T , the loader or shovel is under-trucked. Truck wait times are less with under-trucking than with over-trucking; however, loader or

shovel wait times are higher with under-trucking. One purpose of truck dispatch systems is to control over- and under-trucking to achieve minimum combined loading and hauling cost.

Table 6 presents average truck cycle times for a fleet of one to six 109-t (120-ton) trucks. Because of interference among trucks which causes variation in actual truck cycle times, wait time increases as fleet size increases. In Table 6, the theoretical number of trucks is 4.94 (15.80/3.20) or five trucks.

Availability and Utilization

Availability and utilization do not have standardized definitions and, thus, these terms must be used with care. Irrespective of availability and utilization, percentage of use or actual operating time is needed to estimate truck production. Actual operating time can be defined as the time a truck operates in its designated operating mode such as load, haul, dump, return, wait, and variable delays. This time cannot be estimated using availability and utilization data as commonly defined, but can be estimated by developing detailed time distributions.

Tables 7 and 8 present truck scheduled and actual time distributions, respectively, for a truck fleet operating for different mine schedules and mechanical downtime requirements. The two schedules are for mines operating 5 or 20 shifts per week with mechanical maintenance available 10 or 21 shifts per week, respectively. The two mechanical downtime requirements are for ratios of actual total repair time to actual active operating time of 0.25 or 0.50. The ratio of operating shift actual unscheduled repair time to total actual repair time is 0.20. Because of unscheduled repair time, available operating time (Table 8) is less than scheduled operating time (Table 7). Truck fleet time can be obtained by multiplying truck scheduled and actual times by the number of trucks in the fleet.

The probability of a single truck being available at any specific time, P , can be determined by

$$P = \frac{\text{available operating time}}{\text{scheduled operating time}}$$

Using case C as an example, the scheduled and available operating times in Tables 7 and 8 are 144.00 and 138.33 hr, respectively, resulting in a 0.9606 or 96% probability of a single truck being available.

Assuming that availability of a specific truck is independent of the availability of any other truck, the probability of k trucks being available, P_k , can be determined by

$$P_k = p^k \times (1 - p)^{n-k} \times C^{n-k}$$

where P is the probability of a single truck being available,

Table 6. Truck Cycle Times 109-t (120-ton) Actual Payload

Number of trucks in fleet	1	2	3	4	5	6
Truck cycle time, minutes						
Spot and load	3.20	3.20	3.20	3.20	3.20	3.20
Haul loaded	7.50	7.50	7.00	7.00	7.00	7.00
Turn and dump	0.60	0.60	0.60	0.60	0.60	0.60
Return empty	4.00	4.00	4.50	4.50	4.50	4.50
Wait	0.00	0.00	0.45	1.15	2.40	4.40
Delays, variable	0.50	0.50	0.50	0.50	0.50	0.50
Total	15.80	15.80	16.25	16.95	18.20	20.20

**Table 7. Truck Scheduled Time Distributions
No Scheduled Standby**

Case	A,B	C,D
Scheduled, shifts/week		
Operating	5	20
Maintenance	10	21
Distribution, hours/week		
Operating Shifts		
Operating, scheduled		
Idle	1.50	6.00
Operating, active	29.50	118.00
Delays, fixed	5.00	20.00
Subtotal	36.00	144.00
PM, scheduled	1.50	6.00
Repair, scheduled	2.50	10.00
Repair, unscheduled	—	—
Standby	—	—
Total	40.00	160.00

n is the total trucks in fleet, k are the available trucks, and $C_k^n = n!/k!(n-k)!$

As an example, assuming case C with a probability of 0.9606 and which has a five truck fleet, the probability of four trucks being available is calculated by

$$P_4 = (0.9606)^4 \times (1 - 0.9606)^{5-4} \times \frac{5 \times 4 \times 3 \times 2 \times 1}{4 \times 3 \times 2 \times 1 \times 1}$$

$$P_4 = 0.1677 = 16.77\%$$

Thus, four trucks will be available for operation 16.77% of the scheduled operating time.

Production

Truck production, assuming 100% availability and/or utilization can be calculated by

$$P_t = \frac{60 \times L_t}{t_{tc}}$$

where P_t is the truck production rate based on actual active-operating time, t/h (stph); L_t is the truck actual payload, t (ton); and t_{tc} is the truck total cycle time, minute.

Trips per hour made by a truck, T , can be calculated by

$$T = \frac{60}{t_{tc}}$$

Thus, truck production rate can be calculated by

$$P_t = T \times L_t$$

Truck fleet production, P_f , at a specific time is calculated by

$$P_f = k \times P_t$$

where k are the available trucks in the fleet at a specific time.

Table 9 presents estimated production for a fleet of five 109-t (120-ton) trucks with the truck cycle times in Table 6 and active operating times in Table 8. It should be noted that truck cycle time, truck trips per active operating hour, truck and fleet production per active operating hour, and fleet production per available operating hour are the same for all cases. However, fleet production per scheduled op-

erating hour and per shift are different because these are dependent on active operating hours per shift.

Truck fleet production in Table 9 has been calculated by two different procedures. In the first procedure, production is based on all five trucks being available. Production per available and scheduled operating hours are based on ratios of active to available and scheduled operating times. Production per shift is based on production per active operating hour and active operating hours per shift.

In the second procedure, production is based on the probability of trucks being available during scheduled operating time. Table 10 presents the procedure used to estimate production per scheduled operating hour for case C. For each case, production per available operating hour is based on truck cycle time in Table 6 and the ratio of active to available operating time. Production per shift is based on production per scheduled operating hours per shift.

Table 11 presents the actual time distributions when the truck fleet production requirements are limited to less than fleet production capabilities. This results in truck standby time. In certain situations, such as case D, time distributions and probability of a truck being available may have to be estimated by successive approximations.

It should be noted that the truck fleet production rates presented in Tables 9 and 11 assume that loading equipment is always available as required by trucks. Since this normally is not the situation, the production rate for the loading and haulage system will be less than the production rate for the truck fleet because of the probability of loading equipment not being available.

Truck Requirements

The number of trucks required for the fleet is determined by comparing various fleet production capabilities and costs with production requirements and selecting the lowest cost fleet with adequate production capability. Table 12 presents estimated production for loading and haulage systems using fleets of five and six 109-t (120-ton) trucks with one or two loaders or shovels having an 0.85 or 85% probability of being available.

Loading and haulage system production for five-truck fleets with one loader or shovel having a 1.00 probability is the same as presented in Table 9. With one loader or shovel having an 0.85 probability, production is 85% of production with 1.00 probability. If two loaders or shovels are available, but only one is used at any one time, the probability of at least one loader or shovel being available is 0.9775 or 97.75%. Thus, with two loaders or shovels, production is 97.75% of production with 1.00 probability. Production for the six-truck fleets was estimated by the same procedures as for the five-truck fleets.

If production of 9072 t (10,000 st) per shift is required for the loading and haulage system, this required production for cases A, B, and C can be obtained with (1) five trucks and two loaders or shovels or (2) six trucks and one loader or shovel. For case D, six trucks and two loaders or shovels are necessary for the required production. Loading and haulage costs using the various fleets must then be estimated to determine the lowest cost system.

The methods presented illustrate some of the complexities in estimating truck production and fleet requirements. In determining requirements, it is necessary to consider various truck cycle times, scheduled and actual time distributions, equipment probabilities of being available, and production requirements.

COSTS

Costs generally associated with trucks are ownership and operating costs. Costs for purchase and operation of a specific truck vary widely depending on delivered truck price including shipping cost, current finance charges, truck appli-

cation and loading and haulage conditions, local fuel and lubricant prices, parts availability and prices, local labor availability, skills, and wages, etc. Reliable cost estimates must be based on an accurate assessment of mining conditions and current local data. Thus, methods presented for cost estimating are general and not intended for precise cost estimates.

Truck ownership and operating costs may be presented as annual or hourly costs. Hourly costs usually are based on truck actual operating time which does not include idle, delay, preventive maintenance, repair, and standby times.

Ownership and operating costs, in conjunction with truck fleet production, are used to determine haulage production cost. Haulage cost usually is a major portion of the total mining cost and cost per unit of material mined. However, haulage cost does not reflect the costs for drilling and blasting, loading, haulage road construction and maintenance, supervision, and other activities that may influence haulage cost. Thus, truck fleet selection decisions must be based on total mining cost rather than just haulage cost because the truck fleet interacts with other unit operations and equipment.

Ownership Costs

Ownership costs usually are fixed charges incurred by having equipment at the mine. For tax purposes, these costs may occur either as capital, financial, depreciation, or operating charges and may be determined both as annual and hourly costs.

Truck capital expenditure or depreciable value is delivered truck cost including basic truck and optional equipment,

freight, and erection at the mine, but excluding tires. Truck and optional equipment cost may vary from the manufacturer's list price, depending on the truck market at time of purchase. List price normally includes tires, but trucks frequently are purchased without tires because the mine may purchase tires directly at a lower cost.

Freight cost depends on the truck shipping weight which can be provided by the manufacturer. Freight cost can be substantial for export shipments which also may require import duty payments. Erection cost depends on the degree of truck breakdown for shipment and availability of erection equipment and personnel. Tire cost should be obtained from local tire distributors. Tire cost based on fleet discounts usually is 45 to 55% of tire list price plus tax.

Useful truck life varies widely depending on truck application and loading and haulage conditions, operating methods and procedures, and maintenance programs. Truck life usually is determined by operating hours. Small mechanical drive trucks have a useful life of 20,000 to 30,000 hr and large electric wheel drive trucks have a useful life of 30,000 to 40,000 hr. At some mines, trucks are reconditioned and rebuilt to extend useful life almost indefinitely. Truck operating hours per year depend on truck scheduling and may approach 6000 hr per year for mines operating 20 shifts per week.

Average annual investment can be calculated by

$$\text{average annual investment} = \text{depreciable value} \times \frac{N + 1}{2N}$$

where N is useful life in years. Annual charges for interest, insurance, and taxes are often estimated as percentages of average annual investment.

Truck capital expenditures may be recovered by an annual or hourly depreciation charge. Depreciation charge may be calculated using the truck's depreciable value and useful life or some other method established by tax codes. Charges for interest, insurance, and taxes are often difficult to determine for specific equipment because these may be covered by corporate financing, insurance policies, and tax rates.

Table 13 shows capital expenditures for a 109-t (120-ton) conventional rear dump truck with electric wheel drive. Ownership costs are based on 30,000 hr useful life over a six-year period.

Operating Costs

Operating costs are variable charges directly applicable to truck operation. These normally include fuel, tires and tire repair, preventive maintenance, mechanical repairs, and operator wages. Operating costs normally do not include indirect mine costs associated with mine facilities and supervision. Operating costs can best be estimated from field studies and analysis of mine records.

Fuel cost depends on fuel consumption and local fuel price. Fuel consumption, C_f , in liters per hour (gallons per hour) can be calculated by

$$C_f = \frac{C_{sf} \times P}{\rho_f} \times F_l$$

where C_{sf} is the engine specific fuel consumption at full power, kg fuel/bkW-h (lb fuel per bhp-hr); P is the rated brake power, kW (hp); ρ_f is the fuel density, kg/L (lb/per gal); and F_l is the engine load factor, decimal.

Engine specific fuel consumption at full power ranges from 0.213 to 0.268 kg/bkW-r (0.35 to 0.44 lb per bhp-h) with lower fuel consumption for newer engines with turbo-

* Only one loader used; other loader on standby.

charging and after-cooling. Engine manufacturers provide standard engine performance data, including brake kilowatt (horsepower) and specific fuel consumption, for the entire engine operating speed (rpm) range. Diesel fuel density ranges from 0.84 to 0.96 kg/L (7.0 to 8.0 lb per gal) with No. 2 diesel fuel having a normal density of about 0.85 kg/L (7.1 lb per gal). Fuel density data should be obtained from local suppliers.

Engine load factor is the portion of full power required by the truck. While idling and retarding, a truck engine operates at about 10% of full power with a load factor of 0.10. When moving, load factor is the ratio of rimpull required or used to available rimpull at the velocity at which the truck is moving. During acceleration, the engine usually operates at full power or maximum available rimpull with a load factor of 1.00. For operation at constant velocity, the rimpull required is equal to the resistance to movement. Table 14 presents load factors for the three main truck types when operating under light, average, and heavy haulage conditions. Load factors also can be estimated by computer simulation programs which estimate travel time.

As an example, fuel consumption for a 109-t (120-ton) truck with an 895-kW (1200-hp) engine operating with a 0.40 engine load factor is $97.3 \text{ L/h} [(0.231 \text{ kg/bkW-h} \times 895 \text{ kW} / 0.85 \text{ kg/L}) \times 0.40]$ (25.7 gal per hr) $[(0.38 \text{ lb per bhp-hr} \times 1200 \text{ hp} / 7.1 \text{ lb per gal}) \times 0.40]$ based on a fuel density of 0.85 kg/L (7.1 lb per gal.)

Hourly fuel cost is fuel consumption in liters per hour (gallons per hour) times local fuel price.

Tire cost includes tire replacement and tire repair costs based on tire life. Tire life is affected by tire construction, type, and maintenance; truck application and velocity; haulage road construction, maintenance, grades, and curves; and tire load and position (front, drive, or trailing). Tire life is measured in kilometers (miles) or hours. Based on favorable conditions, E-3 (rock) and E-4 (rock deep tread) bias ply tires can be expected to have a tire life of 40 200 to 56 300 km (25,000 to 35,000 miles) and 56 300 to 72 400 km (35,000 to 45,000 miles), respectively. Radial tires with deep tread can be expected to have a tire life of 64 400 to 80 500 km (40,000 to 50,000 miles). Based on average truck velocity of 16.1 km/h (10 mph), these tire lives are equivalent to 2500 to 3500 hr for E-3 tires, 3500 to 4500 hr for E-4 tires, and 4000 to 5000 hr for deep tread radial tires. Tire life tends to be less for smaller trucks than for larger trucks and is reduced substantially at mines where frequent premature tire failures occur due to overloading, rock cuts, and punctures. Mine experience also has demonstrated that tire life can be increased substantially by very favorable operating conditions.

The hourly tire and tire repair cost is 115% of the hourly tire replacement cost when the tire replacement cost is tire cost divided by tire life in hours. This allows 15% of tire replacement cost for tire maintenance and repair. Tire cost

Table 13. Truck Ownership and Operating Costs 109-t (120-ton), 895-kW (1200-hp) Electric Wheel Drive

Capital Cost		
Standard truck, fob factory		\$675,000
Optional equipment, fob factory		32,000
Freight (193,000 lb at 5.7¢/lb)		11,000
Erection		6,000
Delivered cost		<u>\$724,000</u>
Tires (30.00-51(46) E-4)		43,000
Depreciable value		<u>\$681,000</u>
Truck life		
Years		6
Hours		30,000
Average annual investment		\$397,250
Ownership costs		
	<u>\$/hr</u>	<u>\$/yr</u>
Depreciation	22.70	113,500
Interest (15% of average yearly investment)	11.92	59,588
Insurance (2% of average yearly investment)	1.59	7,945
Taxes (2% of average yearly investment)	1.59	7,945
Total ownership costs	<u>37.80</u>	<u>188,978</u>
Operating costs		
Fuel (0.40 load factor)		
97.3 L/hr at \$0.330/L		
(25.7 gal/hr at \$1.25/gal)	32.13	160,625
Tires and tire repair (4000 hr)		
(\$43,000/4000 hr) × 1.10	11.83	59,125
Preventive maintenance		
(0.20 × \$32.13)	6.43	32,125
Repair (0.40 repair factor)		
[((\$681,000/10,000) × 0.40 × 0.65 × 1.00]	17.71	88,530
Operator	18.00	90,000
Total operating costs	<u>86.10</u>	<u>430,405</u>
Total ownership and operating costs	123.90	619,383

often is reduced by recapping, with recapping prices obtained from local tire distributors.

Preventive maintenance cost includes lubricating oils and greases, filters, and miscellaneous parts and labor required for truck servicing. Preventive maintenance cost is about 20% of fuel cost. A more detailed estimate of both parts and labor can be based on truck service capacities; manufacturer's recommended service intervals; and local oil, grease, filter, and labor costs.

Repair cost includes all truck maintenance expenditures not considered preventive maintenance. This includes both parts and labor for truck overhauls and rebuilds. Two com-

mon methods for estimating repair costs are based on either depreciable value or fuel consumption.

Using depreciable value, repair cost, R_c , in dollars per hour can be estimated by

$$R_c = \frac{V_d}{10,000} \times F_r$$

where V_d is depreciable value and F_r is repair factor. It is important that depreciable value be a current value to reflect current repair cost. Table 15 presents truck repair factors for a range of operating conditions. These repair factors are for mechanical drive trucks and must be reduced for electric wheel drive trucks. Table 16 presents adjustment factors for adjusting the repair factor for truck age. As an example, the estimated average hourly repair cost in Table 13 for the 109-t (120-ton) electric wheel drive truck with a 0.40 repair factor and 30,000-hr life is \$17.71/hr [(\$681,000/10,000) × 0.40 × 0.65 × 1.00]. The estimated repair cost while operating between 20,000 to 30,000 hr is \$22.13/hr [(\$681,000/10,000) × 0.40 × 0.65 × 1.25].

Using fuel consumption to estimate repair cost relates repair cost to engine load factor or work performed by the truck. Using current (1983) parts and labor prices, repair cost for conventional rear dump trucks ranges from \$0.24 to \$0.42/L (\$0.90 to \$1.60 per gal) of fuel for mechanical drive trucks and from \$0.16 to \$0.28/L (\$0.60 to \$1.05 per gal) for electric wheel drive trucks. These repair costs are

Table 14. Truck Engine Load Factors

Truck Type	Load Factor*		
	Light	Average	Heavy
Conventional rear dump	0.25	0.35	0.50
Tractor-trailer	0.35	0.50	0.65
Integral bottom dump	0.25	0.35	0.50

* *Light*: Considerable idle, loaded hauls on favorable grades and good haulage roads.

Average: Normal idle, loaded hauls on adverse grades and good haulage roads.

Heavy: Minimum idle, loaded hauls on steep adverse grades.

Table 15. Truck Repair Factors

	Repair Factor*			
	Favorable	Average	Unfavorable	Very Unfavorable
Conventional rear dump	0.30	0.50	0.75	1.00
Tractor-trailer	0.25	0.40	0.60	0.80

* Repair factors for mechanical drive truck; multiply by 0.65 for electric wheel drive truck.

based on average cost for a 30,000-hr truck life. As an example, repair cost in Table 13 for the 109-t (120-ton) truck could range from \$15.42 to \$26.99/hr using this estimating method.

Operator cost is wages for the truck operator and normally includes base wage, fringe benefits, training, etc.

Production Costs

Haulage production costs usually are presented as cost per tonne (ton) or cost per tonne-kilometer (ton-mile). Cost per tonne (ton) is simply total truck cost divided by the total tonnes (tons) hauled by the truck. Cost per tonne-kilometer (ton-mile) considers the distance the material is hauled and is calculated by total truck cost divided by cumulative tonne-kilometers (ton-miles) which is cumulative weight times distance. As an example, a truck with a 109-t (120-ton) payload making 3.3 round trips per active operating hour with an operating cost of \$86.10/hr (Table 13) has an operating cost of \$0.2397/t (\$0.2174/ton). If the one-way haulage distance is 2438 m (8000 ft), the operating cost is \$0.0983/tonne-km (\$0.1435/ton-mile).

6.5.3 Belt Conveyors

LARRY D. DUNCAN AND BRIAN J. LEVITT

In recent years the changes in the relative costs of equipment, labor, and fuels have made belt conveyors the most economical means of moving large quantities of bulk materials for distances up to several miles. The reliability, high-volume capability, and energy efficiency of belt conveyors have made them dominant for in-plant bulk handling for a long time. The recent costs of petroleum-based fuels and increased emphasis on environmental protection have created more usage of conveyors for overland conveyance of several miles. One of the more recent developments for long distance conveying has been the use of horizontal curves that adapt to terrain and eliminate the need for costly belt transfer structures and drives.

This section on belt conveyors is too limited in scope to serve as a design manual for conveyors. An excellent in-depth guide for detailed design of conveyors is *Belt Conveyors for Bulk Materials*, published by the Conveyor Equipment Manufacturers Association. This section is intended to serve as a guide in the selection of a type of belt conveyor, determination of size, energy requirements, and budget costs for the conventional type of conveyors. This information should enable a mining engineer to do preliminary sizing, system optimization, and capital and operating cost comparisons with different system configurations and alternative transport modes, such as trucks.

GENERAL APPLICABILITY

For surface mining applications, the use of belt conveyors can be divided into the following general applications: (1) in-pit conveyors; (2) overland conveyors; (3) in-plant conveyors; and (4) reclamation-landfill-conveyor systems.

In-Pit Conveyors

With the cost of petroleum-based fuels and increasing restraints on environmental pollution by particulate emissions, belt conveyor systems are being developed to replace mobile vehicles in several applications. Conventional belt conveyor construction, crawler-mounted conveyors, shiftable conveyors with bucket wheel excavators and extendable conveyors are all being used in conjunction with portable crushers and long slope belts.

Overland Conveyors

The advent of high-tension steel cable belting, cable-supported belts, wire rope idler support systems, and horizontal curve designs that reduce transfer stations are helping to reduce conveying costs. Conveying systems that adapt to the terrain are being used in single and multiple flights several miles long. Belt systems are operating in the US that are 24 km (15 miles) long. In Australia, an overland conveying system is in operation that is 50 km (31 miles) long. Cable-supported conveyors, where the cable acts as the tension element rather than the belt, are being used abroad for very long overland systems. The manufacturer claims higher tension capability, therefore a longer conveyor capability, with this system. The use of cable-supported idlers on conventional belt systems can save 10 to 20% of the initial cost of the conveyor structure. Horizontal curve conveyors have been used abroad and recently have found an application in the US.

Common usage for overland belt systems are for 900 to 1200 mm (36 to 48 in.) belts running 3.1 to 6.1 m/s (600 to 1200 fpm). These belts would typically transport 200 to 750 kg/s (800 to 3000 tph) of coal, for example. Energy costs are very low and particulate generation is nil for a covered conveyor system with adequate dust control equipment at the transfer points.

In-Plant Conveyors

In-plant application using conventional belt conveyor construction is the oldest and most common usage of conveyor belts. Conveyors using 20° and 35° troughed idlers are the most common. Belt speeds are typically lower in-plant than for overland conveyors to reduce dusting and belt and chute wear. Typical speeds range from 1.0 to 3.1 m/s (200 to 600 fpm).

Reclamation-Landfill-Conveyor Systems

Belt conveyor systems for landfill and solid waste disposal applications now are being used more often for the same cost and environmental reasons as in-pit and overland systems. Since the discharge point is constantly changing, special conveyors and discharge equipment have been developed for these applications. Some of these are crawler-mounted self-aligning conveyors, shiftable conveyors, extendable conveyors, and portable conveyors.

Normally these conveyors are used in conjunction with wheel or crawler-mounted stackers and trippers. The conveyor system usually advances over its own, self-created fill.

TYPICAL CONVEYOR CONSTRUCTIONS

Several types of belt conveyor designs are available for specific applications. Although more than one type of conveyor may solve a particular materials handling problem, the proper selection will optimize installation and operating costs.

Conventional Stringer Conveyors

Conventional conveyors are turnkey designed and engineered on an individual basis. The construction consists of parallel channel stringer members that support the troughing and occasionally return idlers (Fig. 1). Angle iron support legs are attached to the stringers, with the opposite ends being fixed to embedded anchor bolts, embedded plate, or a conveyor support truss.

A light gage deck plate is sometimes mounted on top of the stringers. The deck plate prevents conveyed material, which may fall off of the side of the belt, from landing on the return strand and becoming wedged between the belt and pulley, causing damage to the belt. V-plow belt cleaners are also usually mounted upstream from a vertical takeup, internal drive system, or tail pulley to keep material from causing belt damage.

Drive and terminal pulley shafts are normally mounted in pillow block bearings, mounted on heavy angle or wide-flange beams. The drive equipment varies depending on the design requirements and space available. Today soft-start devices, electrical or mechanical, are often used on conveyors with drives over 111 855 W (150 hp). They effectively reduce the belt tension and shock imparted by a high torque motor during start-up.

Fig. 1. Conventional stringer conveyor cross section.

Gravity takeups can be horizontally or vertically mounted either between the head and tail pulleys or at the tail pulley. Screw takeups are generally mounted at the tail pulley, but are limited to conveyor lengths of about 30 m (100 ft).

Conventional stringer conveyors are mounted on platforms and inclined ramps indoors and outdoors. They are rigid, easy to clean around, and provide good access for belt and idler maintenance. They are also used in "walk-through" galleries. Walk-through galleries are normally self-enclosing trusses, with roofing, siding and deck plate or floor grating. Galleries come in a wide range of designs, including concrete floors, corrugated arch enclosures, and steel tubes. Totally enclosed galleries must have provisions for heat vents, clean-up, and drains.

Conventional stringer conveyors are by far the most commonly used type today. They are used for in-plant, overland, mobile, and shiftable conveyors. Conventional belt conveyors are limited in their ability to transport up steep inclines. Many users limit slopes to 12° to 15° of incline from the horizontal. Some materials can be conveyed with conventional belts at steeper angles, up to 20°. Tables listing maximum conveyor inclines for many materials are available in the CEMA book *Belt Conveyors for Bulk Materials* mentioned earlier.

When selecting a conveyor slope it is important to consider the effect that frost or ice formation can have on letting material slide down a belt. This might lower a slope 5° to 10° from what otherwise could have been used.

Truss-Mounted Conveyors

Truss-mounted conveyors are commonly used for conveyors that are above grade or platform levels, in lieu of walk-through truss galleries. The troughing idlers are mounted directly to a box truss and the return idlers below or within the framework. This construction is more compact and economical than a walk-through truss, but does not include an enclosed walkway.

In outdoor applications a hood is normally used to protect the carrying belt from wind and rain. A walkway may or

may not be added to the side of the truss for maintenance access. The truss-mounted conveyor is used extensively for portable/mobile conveyor construction, and in mild weather applications in place of walk-through galleries.

Wire Rope Conveyors

The stringers on these conveyors consist of two suspended wire ropes in lieu of channel members (Fig. 2). The wire ropes support the troughing idlers and belt. The return idlers are normally mounted on the support legs which also hold up the wire ropes. Components, head and tail terminals, and takeups are very similar to conventional conveyors.

Wire rope conveyors are used sometimes in overland applications to save capital and installation costs. They are also used extensively on underground applications because they are lightweight, easy to install and disassemble, and tend to be self-aligning.

CONVEYOR TYPES AND ADAPTATIONS

Shiftable Conveyors

These conveyors can be either channel or wire rope stringer supported (channel is most common) and contain the same basic design characteristics of conventional and wire rope conveyors. The difference with this conveyor is its ability to be repositioned with the use of mobile equipment (Fig. 3). Rails mounted on the conveyor support base, coupled with a tractor and mounting assembly, move the conveyor to the desired position. Shiftable conveyors are generally horizontal with the discharge end being elevated for material transfer. They are primarily used in surface mining and land reclamation operations.

Cable Conveyors

Two endless steel wire ropes form the support for the belt as well as carrying the tension forces for this type of conveyor (Fig. 4). The belt rests on the cables, while the tension required to move the belt is transmitted entirely through the endless steel wire ropes. The combination of grooved cable guides built into the belt and a sheave support

Fig.2. Wire rope conveyor (courtesy of Continental Conveyor and Equipment Company, Inc.).

Fig. 3. Shiftable conveyor (courtesy of Continental Conveyor and Equipment Company, Inc.).

system keeps the belt continuously supported and properly aligned.

This conveyor is most economical in lengths over 4.8 to 8.0 km (3 to 5 miles). The cables require a special drive with large sheaves to transmit the drive torque to the cable, which makes them uneconomical for short horizontal applications.

Air-Supported Conveyors

The belt for an air conveyor runs in a concave steel trough and is supported by a thin film of air (Fig. 5). Below the steel trough, a sealed plenum contains pressurized air supplied by a blower. The air passes up through the plenum and escapes from the sides of the belt. The air thus replaces the troughing idlers which would otherwise be necessary. The return belt is supported with conventional return idlers. The drive system and takeup is also similar to a conventional belt conveyor.

Cleat/Sidewall Conveyors

Cleats (or transverse walls) and sidewalls attached to a flat belt comprise this type of conveyor (Fig. 6). The sidewalls

mounted to the base belt are pleated, thus providing an accordion effect around pulleys. The cleats mounted to the sidewalls and base belt enable this type of conveyor to elevate many materials vertically. On long installations, gravity-type takeups can be provided similar to conventional conveyors.

Crawler-Mounted Conveyors

This type of conveyor functions similar to a shiftable type conveyor in that the conveyor is designed to move primarily laterally (sideways). It is mounted on crawlers or tires which are self-transporting. It is made in sections to accommodate changes in slope and is usually equipped with devices to automatically keep it in line laterally. It can be made with movable load points or a movable tripper, which can discharge anywhere along its length to grade or another conveyor (stacker, for example).

This type of conveyor would be used where movement is more frequent than for a shiftable conveyor, where pit (or surface) conditions are not suitable for a shiftable conveyor, or where lengthwise movement must also be accomplished.

Fig. 4. Cable conveyor; typical eight-pulley line stand (courtesy of Cable Belt Conveyors, Inc.).

Mobile Conveyors

These come in a variety of lengths and configurations. Some are self-moving and others must be towed. They can be used in piggyback fashion where several can be added in a string to function as an extendable conveyor, or individually as with a radial stacker.

Pipe Conveyors

The pipe conveyor is a relatively new type of belt conveyor developed in Japan, but now marketed in this country (Fig. 7). It utilizes a special conveyor belt that is wrapped

into a circle or "pipe" shape after being loaded with material. The pipe enclosure is maintained by using idlers, which on a conventional conveyor are normally used to form a trough for the belt. For the pipe conveyor, five or six idlers are used to form a circle. At the discharge point the belt is unwrapped and the material is discharged over a pulley in the conventional way. The return run is also formed into a circle.

The manufacturer states that the pipe conveyor is very "clean" environmentally, since the load is totally enclosed and also the return run does not "dribble" like a conventional belt along the return run. The pipe conveyor is compact in

Fig. 5. Air conveyor (courtesy of Wolverine Corp.).

Fig. 6. Cleat/sidewall conveyor (courtesy of Scholtz-EFS Corp.).

cross section, normally would not require a hood to cover the belt, and can negotiate horizontal curves with a much shorter radius and more simply than a conventional belt.

Sandwich Conveyors

This conveyor adaptation consists of two conveyor belts, one lying on top of the other with the load "sandwiched" in between. It can be used on steep inclines and some designs can double back over themselves forming a C shape. They have found the most usage in self-unloading ships, bringing the bulk cargo from the hold to above deck. They are also utilized as high-angle conveyors using conventional belting and idlers.

Horizontal Curve Conveyors

A few of the preceding types of conveyors, including conventional, cable, and pipe conveyors, can be designed to "go around corners" as well as go up and down hills.

The advantage of this conveyor is the ability of the conveyor path to go around an obstacle such as a hill or building without having to utilize two or more separate conveyors with a transfer station in between each flight. This saves drives, pulleys, transfer structures, and dust emission points at the transfer.

Conventional and cable belt conveyors must have very large curve radii, generally over 500 m (1650 ft). A pipe conveyor type can utilize a much tighter curve.

The design of a conventional-type horizontal curve conveyor is complex and requires many detailed calculations, most often done by a computer. The inherent tension that pulls the belt and load has a component of its pull toward the center of the curve, off of the supporting idlers. The design of a conventional horizontal curve conveyor utilizes idlers (or cable sheaves, on a cable belt) that are tilted, with

Fig. 7. Pipe conveyor (courtesy of Robins Engineers and Constructors).

the higher side toward the center of the curve. The idlers are also normally skewed, putting the idler toward the inside of the curve further ahead in the direction of belt travel than the idler on the outside of the curve.

The combination of tilt and skew utilizes gravity and friction between the belt and idler to counteract the belt pull toward the curve center. Since the belt tension is changing along the belt length, either the tilt or skew must vary to keep the belt near the center of the idler trough. During belt acceleration or deceleration the belt tensions can change radically and quickly. During weather changes (temperature or moisture) the friction between the belt and idlers can change considerably. These factors make the design of horizontal curves very complex, therefore system designs must be handled carefully.

As of this writing, less than 30 horizontal curves are known to exist worldwide. Their use is becoming more common as successful installations are being completed. Most are in mild climates, so the effects of large temperature variations and freezing conditions have not been thoroughly put to the test.

FACTORS IN SIZING A BELT CONVEYOR

Determining the size or width of a belt conveyor in order to handle a specified mass of material per unit time depends upon the following factors: (1) conveyor type, (2) material density, (3) edge distance and percent loading, (4) belt speed, (5) lump size and size distribution, (6) surcharge angle of material, (7) troughing angle and length of individual idler rolls, and (8) belt inclination.

The volume per unit of time that a conveyor handles is determined by the material's cross-sectional area normal to the belt and belt speed.

$$Q = A \times V \times 3600 \quad (Q = A \times V \times 60$$

where Q is the capacity, m^3/hr (cu ft per hr); A is the cross-sectional area, m^2 (sq ft); and V is the belt speed, m/s (fpm).

The mass that the conveyor handles is:

$$T = Q \times D \left[T = \frac{Q \times D}{2000} \right]$$

where T is the capacity, kg/s (ton per hr) and D is density, kg/m^3 (pcf).

The area required to be carried, normal to the belt is then

$$A = \frac{T}{D \times V} \left[A = \frac{33.3T}{D \times V} \right]$$

For an inclined belt the material cross-sectional area normal to the belt decreases, depending upon the shape of the area. For a conventional 35° troughed, equal roll length idler set on an incline of 15° , the loss in area is negligible. For other types of conveyors this loss can be large (cleat sidewalls, for example). The conveyor supplier must be consulted for the particular type conveyor being considered.

This discussion will be limited to conventional troughed conveyors as shown in Fig. 1. For conventional conveyors the factors affecting capacity are discussed in the following.

Material Density

Overestimating the density of the material as it lays on a conveyor can result in an overloaded belt with spillage. If the material density at the specified size gradation is not known, it must be determined in order to accurately size the conveyor.

Edge Distance and Percent Loading

The distance between the edge of the material and belt is the edge distance (see Fig. 1). The "standard" distance used for determining belt capacities is also shown in Fig. 1. The percent loading factor is sometimes used as a safety margin in belt capacity to allow for surge loading and changes in surcharge angles or densities due to size or moisture variations. Typical loading factors are 90% for well-controlled materials and 80% when feed rate or material size and consist are not well-controlled. To apply a safety margin, the theoretical cross-sectional area would be multiplied by the selected load factor.

Belt Speed

Recommended maximum belt speeds are shown in Table 1. Maximizing belt speed minimizes conveyor belt width and, in general, saves capital investment. This is especially true for long overland conveyors. High speed, however, has detrimental effects. Among them are the following: higher wear on idlers and bearings, increased belt wear at the loading point due to material skidding, more dust generation and material degradation, and more wear on discharge chute wear plates. These effects may be partially compensated for by larger idlers and bearings, acceleration of the material at the conveyor load point to match the belt speed through the use of proper chute design or an acceleration conveyor, dust control systems, and careful chute and wear plate design. Many systems are operating at speeds as high as 6 m/s (1200 fpm).

Lump Size and Size Distribution

Lump size influences the width of a conveyor. A guide to lump size and size distribution vs. belt width is shown in Table 2. Dangerous spillage can result from improper lump allowance and loading skirts. Chute size must also be taken into account so lumps do not bridge in the chutes. Most chute designers make chute widths a minimum of two and a half to three times the maximum lump size. Larger lumps or dropping distances must utilize impact idlers in order to save belt and idler damage at the load points. Belting and idler manufacturers provide guides for proper design.

Surcharge Angle of Material

The surcharge angle is related to the material's angle of repose, but is changed because of material vibration and belt flexing between the idler rolls (see Fig. 1). The longer the distance the material is conveyed, the more the surcharge angle tends to flatten. For overland conveyors it may be necessary to decrease the surcharge angle by 5° or more from those values shown in Table 3 to protect from spillage.

Troughing Angle and Length of the Individual Rolls

The most common troughing idler design is three equal length rolls with a troughing angle of 35° . See Tables 4 and 5 for conveyor cross-section capacities for 20° and 35° idlers, respectively. Flat idlers are often used for belt feeders; use of 20° and 45° idlers results in lesser and greater capacities. Narrower belts have more difficulty troughing in steeper idlers. Each application must be checked to insure that the selected belt will conform to the selected troughing angle.

Belt Inclination

Belt inclinations over 15° should be derated 5 to 10% from normal capacities. The most critical factor is the inclination at the load point. High speed conveyors with steep inclination at the load point must be designed carefully so the load settles quickly on the belt at the belt speed. Otherwise, back up will occur in the chute or spillage will result.

Table 1. Recommended Maximum Belt Speeds

MATERIAL BEING CONVEYED	BELT SPEEDS		BELT WIDTH	
	m/s	(fpm)	mm	(in)
GRAIN OR OTHER FREE-FLOWING, NONABRASIVE MATERIAL	2.5	(500)	450	(18)
	3.6	(700)	600 - 750	(24 - 30)

BELT CONVEYOR DESIGN EXAMPLE

The information presented herein provides a quick means of calculating the horsepower required to operate a conventional belt conveyor. This graphical approach is presented in the *CEMA Handbook*. To perform a detailed analysis of a belt conveyor and component selection, the *CEMA Handbook*, belt manufacturer catalogs, conveyor companies, and

engineering firms are suggested sources of additional information. The calculated belt tension and required horsepower may vary based on the friction factors used by the different sources.

The following is an example of how to size a belt conveyor and establish its horsepower requirement by use of a quick graphical method. It is most accurate when used for belt

Table 2. Belt Width Necessary for a Given Lump Size. Fines: No Greater Than 1/10 Maximum Lump Size

Equipment Manufacturers Association, p. 59.

and environmental considerations, the following belt speed is initially selected: 2.79 m/s (550 fpm).

Step 2—Determine surcharge angle.

From Table 3, the surcharge angle is selected based on the known material characteristics: 25°.

Step 3—Calculate cross-sectional area of material on conveyor:

$$A = \frac{T}{D \times V} \quad \left[A = \frac{33.3 T}{D \times V} \right]$$

where A is cross-sectional area, m² (sq ft); T is capacity, kg/s (stph); V is belt speed, m/s (fpm); and D is density, kg/m³ (pcf).

$$A = 0.145 \text{ m}^2 (1.7 \text{ sq ft})$$

Step 4—Determine belt width.

Either Table 4 or Table 5 is selected based on the type of troughing idler used. From Table 5 for 35° idlers, 25° surcharge angle, and the calculated cross-sectional area, use a 1200 mm (48 in.) belt width. Note that at this point the maximum cross section listed in the table can be substituted back into step 3 to calculate a new belt speed with the conveyor 100% loaded.

Step 5—Determine weight per unit length of belt and revolving idler parts.

From Table 6: 61 kg/m (41 lb per ft)

Table 6. Weight Per Linear Foot of Belt and Revolving Idler Parts, kg (lb)

BELT WIDTH mm (in)	MATERIAL DENSITY kg/m ³ (lb/ft ³)			
	800 (50)	1600 (100)	2400 (150)	3200 (200)
450 (18)	17.9 (12)	20.8 (14)	25.3 (17)	25.3 (17)
600 (24)	23.8 (16)	28.3 (19)	34.2 (23)	34.2 (23)
750 (30)	29.8 (20)	35.7 (24)	43.2 (29)	43.2 (29)
900 (36)	41.7 (28)	52.1 (35)	61.0 (41)	71.4 (48)
1050 (42)	50.6 (34)	62.5 (42)	72.9 (49)	87.8 (59)
1200 (48)	61.0 (41)	75.9 (51)	102.7 (69)	114.6 (77)
1350 (54)	71.4 (48)	86.3 (58)	116.1 (78)	132.4 (89)
1500 (60)	89.3 (60)	104.2 (70)	129.5 (87)	147.3 (99)
1800 (72)	110.1 (74)	123.5 (83)	168.2 (113)	193.5 (130)
2100 (84)	151.8 (102)	189.0 (127)	221.7 (149)	245.5 (165)
2400 (96)	174.1 (117)	212.8 (143)	269.4 (181)	269.4 (181)

Adapted From: Belt Conveyors for Bulk Materials, Second Edition Conveyor
Equipment Manufacturers Association, p. 131.

Step 6—Calculate power required to drive an empty conveyor, PR_1 .

From Table 7:

$$PR_1 = \frac{P_1 \times V}{0.5} \quad \left[PR_1 = \frac{P_1 \times V}{100} \right]$$

where P_1 is power to drive empty belt for each 0.5 m/s (100 fpm) belt speed and PR_1 is 13 310 W (17.6 hp).

Step 7—Calculate power required to elevate material, PR_2 .

From Table 8:

$$PR_2 = P_2 \times H$$

where P_2 is the power to elevate material per m (ft) of lift, H is lift m (ft), and PR_2 is 225 349 W (302 hp).

Step 8—Calculate power required to convey material horizontally, PR_3 .

From Table 9:

$$PR_3 = \frac{P_3 \times T}{25} \quad \left[PR_3 = \frac{P_3 \times T}{100} \right]$$

where P_3 is the power to convey material horizontally per 25 kg/s (100 stph) and PR_3 is 45 250 W (60.2 hp).

Adding steps 6, 7, and 8 (PR_1 , PR_2 , PR_3), the total power required, PR

$$PR = 283\,909\text{ W (379.8 hp)}$$

Assuming a 5% power loss through drive components, the required motor power is:

$$PR = 298\,852\text{ W (399.8 hp)}$$

ECONOMICS

When contemplating the installation of a belt conveyor system, engineering economics is a prime consideration. During the conceptual design stage, management may wish to determine any or all of the following: erected, operating, maintenance, taxes, and insurance costs. A present worth analysis is generally used to compare alternatives over the life of the operation. Several books are devoted entirely to the topic of engineering economy. This discussion will be

Table 7. Horsepower Required to Drive Empty Conveyor

limited, therefore, to developing an estimate of installed, operating, and maintenance costs.

Installed Cost

The total installed cost of a belt conveyor includes all mechanical equipment, supporting structural steel, and erection. Typically a conveyor supplier does not provide earthwork, foundations, external electrical wiring, and controls. These are often engineered by an engineering company and erected by construction contractors. Chutework and its support are generally provided by the conveyor vendor and should be added to the developed cost estimate.

A range for the approximate cost per meter (cost per linear foot) for conventional stringer conveyors, wire rope conveyors, and truss mounted conveyors is given in Table 10. Since wire rope conveyors are less expensive than conventional stringer conveyors, they will fall in the lower part of the range. The installed cost of the conveyor, without its drive, is obtained by multiplying the incremental cost by the

total length. From the power calculation presented previously, an erected drive assembly cost can be selected from Table 11 and added to the erected conveyor cost established from Table 10. The resultant cost includes an allowance for railroad ties to support a conventional stringer or a wire rope conveyor. Permanent foundation costs can vary greatly depending on soil conditions, terrain, and conveyor loads. Permanent foundation costs, therefore, have not been included in the cost tables.

Normal earthwork costs for overland conveyors up to 1200 mm (48 in.) wide, range from \$16.40 to \$32.80 per m (\$5 to \$10 per ft). This range includes grubbing, a graded surface, ballast (if railroad ties are used for support), gravel service road, and drainage ditches.

Electrical equipment and installation costs normally add approximately 15% to the combined total from Tables 10 and 11. This includes conveyor safety switches, controls, wiring, switchgear, and installation. Pole lines or a power connection for a remote location are not included.

Table 10. Installed Cost for Conveyor Types
Belt Width, mm

Table 11. Installed Cost for Drive Equipment

Many conventional stringer conveyors are suspended between supports and are in inclement climates and, therefore, are supported by totally enclosed gallery type trusses. For spans of 22.9 to 45.7 m (75 to 150 ft), the cost of the enclosed truss is approximately \$2575 to \$2950 per m (\$785 to \$900 per ft) respectively. This cost is for single conveyors up to 1200 mm (48 in.) wide and includes erection, but not the conveyor (see Tables 10 and 11).

Bents support gallery type trusses or truss-mounted conveyors. The cost of bents for a typical 30.5 m (100 ft) span truss can be interpolated through a height range from 1.5 to 48.8 m (5 to 160 ft) at \$825 to \$131,000, respectively, for each bent required.

Operating and Maintenance Cost

The operating cost of a conveyor system basically is comprised of two parts: labor and power. The cost for operating labor can vary greatly depending on the number of conveyors, their location, operating time per day, type of operating facility (mine, quarry, power plant, etc.), and the degree of automation. Depending on these factors, the number of operating personnel who periodically observe the system operation and the control room operator or local control operator(s) man-hours can be determined. This is best established by the operating company based on established policies, but can be approximated by the engineer.

The cost of power can also vary greatly. A good preliminary approximation is 5 to 6¢ per kW/h, based on actual power consumed. Declining conveyors, regenerative in nature, require special considerations since the conveyor will generate instead of consume power.

The annual cost of maintenance can be approximated using a rule of thumb of 1 to 2% of the installed conveyor cost developed from Tables 10 and 11.

All of the estimated costs presented herein are based on second quarter, 1985 dollars, and should only be used to establish an order-of-magnitude cost for a conveyor.

6.5.4 Ore Passes

WILLIAM R. GOODNER

Ore passes are raises, either vertical or inclined, generally constructed for transporting ore long distances downward from a dumping facility to a collecting point. Their characteristic of *surge* containment or storage capability sets ore passes apart from other types of raises. This capability facilitates transferring the ore to a crusher or another mode of transport (railcar, conveyor, skip, etc.) through a gate or feeder at a controlled rate. The lower portion of an ore pass, having a relatively small cross-sectional area, may be enlarged (slashed) to increase its storage capacity, or intermittent level control gates may be installed for the same purpose. Existing ore passes have round or rectangular cross sections with areas from under 1 m² (10 ft²) to 16 m² (172 ft²) and larger, and lengths over 457 m (1500 ft). They may be unlined or lined completely or partially with timber, concrete, or steel plate.

An ore pass in a surface-mining operation would probably be feasible only if:

1. The shape of the ore body and its location relative to the surrounding terrain (Fig. 1) will permit construction of an ore pass to a belt conveyor or train system in an adit at a level below the ore body (this is an ideal situation for economical utilization of an ore pass); or,
2. The depth of an ore body is such that at some mining level (Figs. 2 and 3), the cost of constructing and operating a conveyor and/or skip system and ore pass in conjunction with an existing pit haul system compares favorably with the cost of uphill hauling with the existing system (this is with the assumption that it is impractical to locate a conveyor and/or skip in the benched area of the pit); or
3. The shape and location of the ore body dictates surface mining preceding or concurrent with an underground mining operation (Fig. 4).

Characteristics of both the ore pass and the ore affect flowability. These characteristics may prevent efficient use of an ore pass and must also be considered. Generally included are:

1. Integrity of the ore-pass wall, i.e., geological conditions should be adequate (within acceptable erosion limits) to withstand the impact and abrasion of the falling ore; walls containing loose rock will require proper lining;
2. Degree of ore-pass wall roughness;
3. Dimensions of the ore pass, i.e., cross-sectional area, height of vertical free fall, length of an inclined pass, etc., related to hangups, and crushing and packing of the ore;

4. Ore particle size and distribution in the ore mass, especially as regards large quantities of fines;

5. Moisture content of the ore; high content in association with fines (but less than *mud*) develops high shear strength in the ore mass; conversely, dry fines combined with the copious quantities of entrained air may pose a serious ventilating problem—even necessitating a separate ventilation raise;

6. Various ambient conditions that may affect both ore pass and ore, e.g., rain, snow, freezing and/or icy conditions, etc.

The design of an ore pass is predicated on the desired flowrate and storage/surge capability under the conditions imposed by the aforementioned characteristics. The mechanics of ore flow (Fig. 5) take into account various aspects of ore mass analysis (primarily, unit weight, cohesive strength, and internal friction) as they affect the forces normal to the pass walls, and the resultant ore-pass resistance to ore mass movement. The final determination becomes quite involved and may require enlisting the services of a bulk-solids-flow testing consultant.

If there is a choice between using a vertical or an inclined ore pass, the advantages and disadvantages of each should be noted.

1. A vertical pass is shorter for the same elevation difference.
2. Generally, ore has less contact with the walls of a vertical pass; therefore, there is less wear, rough walls have less effect on ore flow, and there may be less need for lining.
3. There is more autogenic crushing in a vertical pass.
4. Vertical passes require no knuckle and have none of the problems inherent with knuckles.
5. Vertical passes are more easily slashed to increase storage capacity.
6. Mechanical boring of a vertical pass is cheaper, faster, and more accurate.
7. The horizontal component of an inclined pass replaces other more expensive horizontal transport methods.
8. Ore velocity is usually less in an inclined pass; therefore, there is less problem with entrained air, fragmentation, and dust.

9. For some conditions of ore and ore pass, arching is less likely in an inclined pass due to the imbalance of normal forces (see Fig. 5).

In the past, there have been designers who advocated

Fig. 1. Truck-crusher-ore pass-belt conveyor (or train).

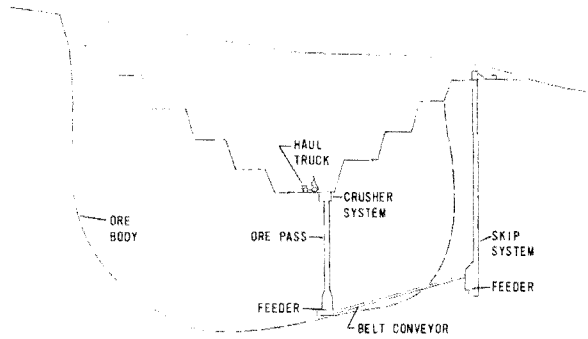

Fig. 2. Truck-crusher-ore pass-belt conveyor-skip hoist.

providing an inspection raise alongside the ore pass; however, the present consensus is that this is unnecessary if the ore pass is properly designed and constructed.

Ore-pass construction using state-of-the-art drill-and-blast techniques is gradually being replaced by mechanical raise-boring. This transition has been accelerated by the decreasing number of miners qualified for drill-and-blast

Fig. 4. Combined surface and underground mining transport systems.

Fig. 3. Truck-crusher-ore pass-skip hoist.

methods. Raise-boring is also attractive because it is less hazardous for the miners, is faster and less costly, and produces a smoother wall than blasting. The advent of raise-boring contractors has made this method even more appealing; mining companies need not be saddled with the irretrievable costs of owning boring machinery which is used only occasionally. At the time of this writing (1982), raise-boring is rapidly coming into its own. Better materials, improved design of machinery, and advanced miner know-how are continuing to reduce costs and time requirements.

It is somewhat difficult to establish a cost of an ore pass to compare with other transport methods. Cost considerations should include amortization and operating (maintenance) costs along with personnel costs. The operating cost of an ore pass is generally very low and might be considered a tradeoff for capital cost. Following are estimated costs for

Fig. 5. Mechanics of ore flow in a circular ore pass.

- P_n : Pressure normal to side-wall (Function of γ, ϕ, c, H, D and θ)
 r : Resistance of wall to ore-mass movement (Function of $\gamma, \mu, \phi, c, H, D$ and θ)
 W : Pressure on arch (Function of γ, H and D)
 γ : Weight of ore per unit volume; μ : friction coefficient of ore and wall;
 ϕ : angle of ore mass internal friction; c : cohesive strength of ore mass;
 H : depth of ore mass; D : ore pass diameter; θ : angle of ore pass above horizontal.

various combinations of transport components. The estimates are derived from information given in *Capital and Operating Cost Estimating System Handbook* (Anon, 1979) and are based on a hypothetical 25 650 t/d (28,275 st pd) in order to stay within the limits given in that publication. Truck travel time per trip includes wait, load, haul, wait, dump, and return. Estimates for ore passes, tunnels, and shafts include a five-year (330 production days per year) amortization.

Assume eight trucks for three shifts and nine trucks for one shift, each hauling an average 95 t (105 st) per trip up an 8% grade from a 244 m (800 ft) depth. Haul speed 8.1 km/h (5 mph), return speed 32.2 km/h (20 mph). Assume 40 minutes per trip. Estimated cost: truck hauling, \$30,442 per day (see Fig. 6).

Three trucks on three shifts each hauling an average 95 t (105 st) per trip, level or down an 8% grade [maximum 24.4 m (80 ft) elevation difference assumed]. Haul speed 8.1

Fig. 6. Truck-crusher (at ground level).

km/h (5 mph), return speed 16.6 km/h (10 mph). Assume 15 minutes per trip. Dump through crusher system to a 209 m (600 ft) ore pass and feeder system to a belt conveyor in an 853 m (2800 ft) adit, or to a train (with trolley locos) in a 914 m (3000 ft) adit (see Fig. 1).

Estimated cost:	truck hauling	\$ 2571 per day
	ore pass	21 per day
	conveyor adit	108 per day
	belt conveyor	<u>369 per day</u>

Estimated total with conveyor \$ 3069 per day

Estimated cost:	train adit	\$ 174 per day
	train	<u>6504 per day</u>

Labor cost herein is based on the assumption that crew for underground rail system is one-third that for surface spur or main line.

Estimated total with train \$ 9270 per day

Trucks and ore pass are the same as shown in Fig. 1. Belt conveyor is 252 m (828 ft) long, inclined 15° upward to a 365.8 m (1200 ft) deep skip hoist system (see Fig. 2).

Estimated cost:	truck hauling	\$ 2571 per day
	belt conveyor tunnel	32 per day
	belt conveyor	558 per day
	skip hoist shaft	1070 per day
	skip hoist	<u>3497 per day</u>

Estimated total \$ 7728 per day

6.5.5 Scrapers

RONALD M. HAYS

TYPES AND APPLICABILITY

Tractor-scraper units have a track or wheeled (rubber-tired) tractor and a wheeled scraper connected by a hitch. Rubber-tired tractors and scrapers may have one or two axles. Currently, the most popular tractor-scrapers have a one-axle tractor with the engine *overhung* forward of the single drive axle and a one-axle scraper with the axle at the rear of the scraper. These scrapers operate well on adverse grades, can *duckwalk* through poor ground or mud, and have a small turning circle.

Tractor-scrapers are powered by a single diesel engine on the tractor or dual diesel engines with one on the tractor and the other on the rear end of the scraper. Dual-engine or tandem-powered machines with single-axle tractor and scraper offer greatest traction because all gross vehicle weight (GVW) is distributed on drive axles.

Tractor-scrapers are designed for either pull-, push-, or self-loading. Pull-loading scrapers use a track or wheeled tractor with adequate pulling force and traction to load the scraper. Push loading of conventional scrapers usually requires the assistance of a track or wheeled dozer (pusher) for efficient scraper loading. These scrapers may be either single engine or tandem powered. Two conventional dual engine scrapers may operate in a push-pull arrangement by

coupling the scrapers together. The front scraper is loaded first while being pushed by the rear scraper. The rear scraper then is loaded while being pulled by the loaded front scraper. Self-loading scrapers have an elevating mechanism or auger to raise material into the scraper. These various types of tractor-scrapers are illustrated in Fig. 1.

In surface mines, scrapers are used to excavate and haul a wide range of materials, including top soil, clay, silt, sand, gravel, well-broken rock, and ripped coal or rock. Scrapers have heaped capacities and rated payloads ranging up to 33.6 m³ (44 cu yd) and 47 t (52 ton) for general use and 42.8 m³ (56 cu yd) and 37 t (41 ton) for coal.

Conventional single engine scrapers load difficult-to-excavate materials when pushed by one or more track dozers. The pushing force usually ranges from 1 to 2 kg (lb) of push per kilogram (lb) of scraper payload. Table 3 (in Section 6.5.2) presents tractive coefficients which can be used to determine pushing capabilities of track and wheeled dozers. Conventional single engine scrapers are designed with good gradeability, having 182 to 243 kg/kW (300 to 400 lb per hp). These scrapers have fair traction with 50 to 55% of weight distributed on the drive axle.

These scrapers are the most efficient scrapers in terms of rated payload to gross vehicle weight (GVW) with payload

Fig. 1. Tractor-scraper types.

comprising about 45% of GVW. Principal advantages of conventional single engine scrapers are the wide range of materials which can be loaded, short load time, and favorable machine weight. Principal disadvantage is the need for pusher(s), requiring synchronization of scrapers and pusher(s). These scrapers perform best on relatively flat haulage roads over medium to long haul distances.

Conventional dual engine scrapers when pushed by track dozer(s) can load the same materials as single engine scrapers. However, when two scrapers operate as push-pull scrapers, these scrapers are limited to easily excavated materials. Conventional dual engine scrapers are designed with excellent gradeability, having 122 to 281 kg/kW (200 to 300 lb per hp). Because of this excellent gradeability, dual engine scrapers can operate at a higher velocity than single engine scrapers. Traction is the maximum possible because these scrapers have all the weight distributed on drive axles and have locking differentials to prevent any drive wheel from spinning free. Because of the additional drive train, tandem-powered scrapers have a higher net vehicle weight (NVW) for the same rated payload than single engine scrapers. Thus, the payload comprises a slightly lower percentage of GVW. Principal advantages of conventional dual engine scrapers are the wide range of materials that can be loaded when using dozer pusher(s), short load time, excellent gradeability, excellent traction, and ability to operate without dozer pusher(s) when operating in push-pull arrangement. These advantages can result in increased production. Principal disadvantage is increased machine weight resulting in higher ownership and operating costs. These scrapers perform best on poor ground conditions, steep grades, and short to medium hauls.

Self-loading scrapers only can load easily excavated materials. Elevating scrapers can load materials such as top soil, sand, and fine gravels without any rock. Auger scrapers extend the range of materials loaded and are now used for ripped coal. The ability of self-loading scrapers to operate on poor ground, steep grades, and long hauls depends on whether the machine has single or dual engines. However, self-loading scrapers have increased NVW for the same payload because of the modified design and weight of the self-loading mechanism. The principal advantage of self-loading scrapers is the ability to operate independently of other equipment such as a dozer or another scraper for assistance during loading. Principal disadvantages are limited range of materials that can be loaded, increased loading time, and increased machine weight.

DESIGN, SPECIFICATIONS, AND PERFORMANCE

Various types of tractor-scrapers are designed to perform best under specific loading and haulage conditions.

Design

Drive components providing power to the drive wheels consist of high speed diesel engines, torque converter, power shift transmission, differential, and final reduction gearing. Engine power output can range up to 410 kW (550 hp) for tractor engines and 298 kW (400 hp) for scraper engines. Differentials may be of a nonspin or locking design.

Tractor-scrapers are equipped with service, emergency, and parking brakes. These machines also may have a hydraulic retarder integral with the transmission for braking on favorable grades.

Tractor-scrapers use either bias ply or radial tires. These usually are wide base traction (E-2) or rock (E-3) tires. Tires

must have adequate load-carrying capacity and tonne-kilometers per hour (ton-miles per hour) rating.

The conventional scraper has three basic operating parts: bowl, apron, and ejector. The bowl forms a box with a rigid floor and sides. The floor is cut off forward of the center line and fitted with a cutting edge. The apron is the box front, which is opened to load and empty the bowl and closed during haulage. The ejector is the bowl rear which moves forward to force material out of the bowl. Fig. 2 shows the arrangement of bowl, apron, and ejector.

For the elevating scraper, the apron is replaced by an elevator consisting of two roller chains carrying crossbars or flights. The elevator bottom is near the bowl cutting edge with the elevator sloping back over the bowl. Elevator flights dig and lift material into the bowl. Ejection is usually accomplished by first moving the bowl backward against the

Fig. 2. Scraper bowl, apron, and ejector.

stationary ejector to open the space between the elevator and bowl cutting edge and then moving the ejector forward to complete unloading.

Specifications

Tractor-scraper manufacturers provide important machine specifications such as rated payload, heaped and struck volumetric capacity, engine kilowatt (horsepower), net vehicle weight (NVW), gross vehicle weight (GVW), weight distributions, clearance turning circle, width of cut, maximum depth of cut and spread, clearance under axles and bowl, and overall dimensions. Tractor-scrappers can be equipped with optional equipment to reduce maintenance, protect equipment, and increase productivity.

Performance

Drive train performance and retarding capabilities are characterized by performance and retarding curves, respectively. The drive train may have from 4 to 11 forward speeds and one or two reverse speeds. These curves are similar and used and adjusted in the same manner as performance and retarding curves for trucks. Travel time for the scraper to travel from one location to another is based on performance and retarding curves, net vehicle weight (NVW), actual payload, haulage road grade and rolling resistance, velocity limits and other operating constraints, and operator performance. Scraper theoretical travel time can be calculated using the same methods and computer simulation programs utilized to calculate truck travel time.

CYCLE TIMES

Two cycle times are important in estimating or evaluating scraper production: tractor-scraper and pusher cycle times.

Scraper Cycle Time

Tractor-scraper cycle time is the time required for the scraper to complete a single cycle including load, haul loaded, spread, return empty, wait, and delay. Scraper production is dependent on average actual payload and average cycle time. If pusher(s) are necessary, scraper fleet and pusher(s) must be matched to ensure adequate pushers with sufficient pushing force.

Load time depends on scraper type, material characteristics, pushing or pulling force, and operating conditions. Table 1 presents load times for various tractor-scrappers when operating under favorable, average, and unfavorable conditions. It is important that load time be minimized for economical scraper operation.

Travel time includes haul loaded and return empty times. These depend on the same factors and are calculated by the same computer programs as truck travel times. Manufac-

Table 1. Tractor-Scraper Load Times

	Load Time, Minutes		
	Favorable	Average	Unfavorable
Conventional, push loaded			
Single engine	0.40	0.70	1.00
Dual engines	0.35	0.60	0.90
Conventional, push pull			
Dual engines*	0.60	0.90	1.50
Elevating			
Single engine	0.60	0.90	1.30
Dual engines	0.45	0.70	1.00

* Time for loading both scrapers.

Table 2. Tractor-Scraper Spread Times

	Spread Time, Minutes		
	Favorable	Average	Unfavorable
Conventional			
Single engine	0.30	0.60	1.00
Dual engines	0.30	0.50	0.90
Elevating			
Single engine	0.40	0.70	1.10
Dual engines	0.30	0.60	1.00

turers provide distance vs. travel time graphs as a function of total resistance for various tractor-scrappers operating empty and loaded. These graphs can be used to estimate approximate travel times for haulage roads with simple profiles. Operating constraints such as velocity limits are required on downhill or favorable grades and curves. These limits depend on scraper design and load. Tractor-scrappers have a low center of gravity favoring stability, but the machine may *jackknife* under certain operating conditions.

Spread time is the time required for a scraper to maneuver and dump material. This time depends on scraper type, material characteristics, ground conditions, and operating conditions. Table 2 presents spread times for various tractor-scrappers. Material usually is spread in thin layers so that the scraper can maintain velocity and minimize equipment necessary to grade the dump.

Wait time occurs when the scraper must wait for a pusher at the loading area or for assistance at the dump. Wait time is caused by an inadequate number of pushers, inadequate pushing force causing long and variable load times, variable size scrapers with variable performance characteristics, poor weather conditions, and operator performance causing variation in cycle times.

Delay time includes variable delays which are not predictable as to time of occurrence and duration. These delays include haulage road maintenance, preparation of cut and dump area, driver relief stop, etc.

Total scraper cycle time is the summation of load, haul loaded, spread, return empty, wait, and delay times.

Pusher Cycle Time

Pusher cycle time is the time required for loading the scraper, boosting the scraper out of the cut, returning pusher for the next scraper, maneuvering the pusher, waiting, and delays. Pusher load time is the same as the scraper load time. Boost time usually ranges from 0.06 to 0.18 min. Pusher return and maneuver times depend on the pusher pattern.

Three commonly used pusher patterns are: (1) back-track loading, the simplest pattern, for short wide cut areas; (2) chain loading for long narrow cuts; and (3) shuttle loading for long cuts with loaders alternating direction. These patterns are illustrated in Fig. 3. Note that back-track loading is the only pattern that requires the pusher to operate in reverse and to return to the beginning of the cut.

Table 3 presents pusher cycle times without wait and delay times for various pusher patterns. Wait time occurs when the pusher must wait for a scraper. Wait time may be caused by an inadequate number of scrapers, variable size scrapers with variable performance characteristics, poor weather conditions, etc. Delay time includes variable delays such as preparation of the cut, driver relief stop, etc. In many cases, wait time can be used to prepare the cut and reduce delay time.

Fig. 3. Pusher patterns.

The theoretical number of scrapers that a pusher can service, N_p , can be derived by

$$N_p = \frac{t_{sc}}{t_{pc}}$$

where t_{sc} is the total theoretical scraper cycle time (no wait time) in minutes and t_{pc} is the total theoretical pusher cycle time (no wait time) in minutes.

PRODUCTION AND COSTS

Tractor-scraper production, fleet requirements, and costs are estimated and evaluated by the same general methods used for trucks. Actual operating time can be estimated by developing detailed scheduled and actual time distributions. Probability theory also can be used to estimate scraper availability.

Table 3. Pusher Cycle Times Without Wait and Delay Times

	Pusher Cycle Time, minutes*		
	Favorable	Average	Unfavorable
Pusher pattern			
Back track loading	0.75	1.25	1.80
Chain loading	0.60	0.95	1.40
Shuttle loading	0.60	0.95	1.40

* For tandem pushers, multiply pusher cycle time by 1.20.

Production

Scraper production, assuming 100% availability and/or utilization, can be calculated by

$$P_s = \frac{60 \times L_s}{t_{ts}}$$

where P_s is the scraper production rate based on actual active operating time, m^3/h (cu yd per hr) or tonne per hour (stph); L_s is the scraper actual payload, m^3 (cu yd) or tonne (ton); and t_{ts} is the scraper total cycle time in minutes.

Scraper production commonly is based on bank volume. Since scrapers usually are filled to heaped (1:1) capacity, bank volume of material in the scraper can be determined by

$$L_s = C_s \times F_s$$

where L_s is the scraper actual payload, bank m^3 (cu yd); C_s is the scraper rated heaped (1:1) capacity, m^3 (cu yd); and F_s is the material swell factor, decimal.

Trips per hour made by the scraper, T , can be calculated by

$$T = \frac{60}{t_{ts}}$$

Thus, scraper production also can be calculated by

$$P_s = T \times L_s$$

Fleet production, P_f , at a specific time is calculated by

$$P_f = k \times P_s$$

where k is number of available scrapers in the fleet. The number of scrapers required for the fleet is determined by comparing various fleet production capabilities and costs.

Costs

The ownership cost for scrapers is determined in the same manner as for other rubber-tired equipment, with depreciable value being delivered scraper cost less tires. Useful scraper life ranges from 12,000 to 16,000 hr.

Operating costs include fuel, tires and tire repair, preventive maintenance, mechanical repairs, cutting edge replacement, and operator wages. Hourly fuel consumption and cost can be calculated by the same method described for trucks. Table 4 presents tractor-scraper engine load factors when operating under light, average, and heavy loading and haulage conditions. Scraper tire life is greatly influenced by ground conditions, loading procedure, and operator experience as well as tire construction, type, loads, and maintenance; scraper velocity; and haulage road design, construction, and maintenance. As an example, tire life can be shortened greatly due to excessive wear and cuts by tire

Table 4. Tractor-Scraper Engine Load Factors

	Load Factor*		
	Light	Average	Heavy
All tractor-scrappers	0.40	0.55	0.75

* *Light*: Considerable idle, loaded hauls on favorable grades with low rolling resistance.

Average: Normal idle, load hauls on level grades with low rolling resistance.

Heavy: Minimum idle with steady cycling, loaded hauls on adverse grades with high rolling resistance.

Table 5. Tractor-Scraper Repair Factors

	Repair Factor*			
	Favorable	Average	Unfavorable	Very Unfavorable
Conventional, push loaded				
Single engine	0.30	0.65	1.00	1.30
Dual engines	0.35	0.70	1.05	1.40
Conventional Push pull				
Dual engines	0.35	0.72	1.08	1.45
Elevating				
Single engine	0.40	0.75	1.10	1.50
Dual engines	0.45	0.80	1.15	1.60

* Based on 0-16,000 hr tractor-scraper life.

spinning when loading ripped rock. Typical life of E-3 bias ply tires is 2000 to 3000 hr for drive wheel tires and 2500 to 3500 hr for tires on trailing axles. Hourly tire and repair cost is 115% of hourly tire replacement cost.

Preventive maintenance cost, including lubricating oils, greases, filters, miscellaneous parts, and labor, is about 15% of fuel cost. A more detailed estimate can be made based on specific machine data and local costs. Hourly repair cost, R_c , can be estimated by

$$R_c = \frac{V_d}{10,000} \times F,$$

where V_d is the depreciable value and F is the repair factor. Table 5 presents tractor-scraper repair factors for a range of operating conditions. Cutting edge replacement cost varies widely depending on material loaded, loading procedure, and operator experience. This cost may be 2 to 10% of the repair cost. Operator wages normally include base wage, fringe benefits, training, and other operator related costs for operating the scraper.

Scraper loading and haulage costs usually are determined as cost per bank cubic meter (cubic yard). These include costs for both tractor-scraper and, if used, pusher.

Fleet Production and Cost

Table 6 presents estimated fleet production and costs as well as cost per bank cubic meter (cubic yard) for conventional single engine scrapers and pusher loading and excavating loose earth with a bank bulk density of 1780 kg/m³ (3000 lb per cu yd). At a loading velocity of 2.74 km/h (1.7 mph), the track dozer can provide 34 020 kg (75,000 lb) of push which is slightly more than required pushing force of 33 750 kg (74,400 lb). Thus, the track dozer can provide adequate pushing force to load the scraper. As the number of scrapers in the fleet increases, scraper load, travel, spread, and delay times remain constant, but scraper wait time increases because of nonsynchronization of scrapers and pusher. As an example, there is no wait time with three scrapers because there is excessive pusher capacity. As the scraper wait time increases, pusher wait time decreases.

Hourly scraper unit costs in Table 6 decrease as the number of scrapers increase because lighter work cycles result from increased wait times. However, hourly pusher unit costs increase as the number of scrapers increases because the pusher has a heavier work cycle. Based on scraper and pusher cycle times, the pusher theoretically can serve 5.7 (8.00 min/1.4 min) scrapers. However, the lowest cost per bank cubic meter (cubic yard) occurs with five scrapers.

Table 6. Tractor-Scraper Fleet Production and Costs

Material	
Description:	Loose earth
Bank density:	1780 kg/m ³ (3000 lb/cu yd)
Loose density:	1424 kg/m ³ (2400 lb/cu yd)
Swell factor:	0.80
Traction coefficient:	
Rubber tires	0.45
Track	0.60
Time distribution	
Scheduled:	10 shifts/week
Active operating time:	5.50 hr/shift
Scraper	
Type:	Conventional single engine, 336 kW (450 hp)
NVW:	43 090 kg (95,000 lb)
Capacity:	23.7 m ³ (31 cu yd) heaped
Rated load:	34 020 kg (75,000 lb)
Weight distribution, drive wheels:	
Empty	70%
Loaded	55%
Actual load:	23.7 m ³ × 1780 kg/m ³ × 0.80 = 33 750 kg (74,400 lb)

Table 6.—Continued

Tractive force—traction limitation:					
Empty	$0.45 \times 43\,090\text{ kg} \times 0.70 = 13\,573\text{ kg (29\,925 lb)}$				
Loaded	$0.45 \times 76\,840\text{ kg} \times 0.55 = 19\,018\text{ kg (41\,927 lb)}$				
Tractive force—rimpull limitation at 2.74 km/hr (1.7 mph): 29 485 kg (65,000 lb)					
Cut dimensions:					
Length	27.4 m (90 ft)

6.5.6. Wheel Loaders

RONALD M. HAYS

LOAD-AND-CARRY APPLICATIONS

Wheel front-end loaders commonly are used as load-and-carry units where the loader excavates, transports, and dumps or spreads material. Typical load-and-carry applications are:

1. Load at face and carry to hopper, crusher, stockpile, dump, etc.
2. Strip, carry, and stockpile topsoil.
3. Load from stockpile or surge piles and carry to hopper.
4. Load, carry, and spread material for construction and maintenance of roads, dikes, settling ponds, etc.

The wheel loader has excellent mobility and is widely used for small or intermittent load-and-carry applications. Larger wheel loaders also are used as primary haulage equipment for short transport distances of up to 183 m (600 ft) with level to gentle slopes.

DESIGN, SPECIFICATIONS, AND PERFORMANCE

Wheel front-end loaders used in mining applications usually are designed with a center-articulated design and a rear-mounted diesel engine. Power is transmitted to all four wheels by either a mechanical drive train or electric wheel motors.

Wheel loaders can be equipped with bias ply, radial, or beadless tires. The Tire and Rim Association (T&RA) code identification for loader tires is the same as for dozer tires. The beadless tire consists of a carcass covered by a replaceable steel-reinforced rubber mounting belt with anchor plates and mounting lugs and steel shoes bolted directly to the mounting belt. When used in load-and-carry applications, tires must have adequate tonne-kilometer per hour (ton-mile per hour) rating as well as adequate load carrying capacity. Since loader tire load limits often are based on a peak speed of 8.0 km/h (5 mph) and maximum one way distances of 76 m (250 ft), tire loads must be reduced for the higher velocities and longer transport distances often encountered in load-and-carry applications.

Wheel loader manufacturers provide important machine specifications such as rated payload, nominally heaped (2:1) and struck volumetric capacity, engine kilowatt (horsepower), operating weight, weight distribution, tipping loads, carry position, bucket width, clearance circle, and overall dimensions. For wheel loaders, the payload is only 15 to 25% of loaded operating weight, resulting in a relatively inefficient haulage unit.

Wheel loader drive train performance and retarding capabilities are characterized by performance and retarder

curves, respectively. Wheel loaders with mechanical drives commonly have two to four forward and reverse gears. Reverse velocities are important in load-and-carry applications since the loader may travel the same distance in reverse as in forward. These curves are similar and used and adjusted in the same manner as performance and retarding curves for other mobile equipment.

LOADER CYCLE TIME AND PRODUCTION

When used in load-and-carry applications, loader cycle time consists of load, travel, dump, maneuver, and delay times. Load time is the time to dig into the bank and load the bucket. Load time depends on material characteristics, loader digging forces and bucket size, loading procedure, and operator skill. Travel time includes time for travel both loaded and return empty between the face or pile and the dump or spread point. During travel the bucket should be near the carry position to maintain a low center of gravity. Travel times can be calculated by the same computer programs used to calculate travel time for other mobile equipment. Manufacturers also provide distance vs. travel time graphs as a function of total resistance for loaded and empty wheel loaders. These graphs usually are satisfactory for short travel distances with simple haulage profiles. Dump time is the time to raise and dump the bucket or spread material at the dump or spread point. Dump time depends on the loader's hydraulic cycle times and dumping or spreading procedure. Maneuver time is the time required for the loader to maneuver and possibly turn at both the face or pile and dump or spread point. Delay time includes nonpredictable variable delays due to area maintenance and cleanup, driver relief stop, etc. Loader total cycle time for load-and-carry applications is the summation of load, travel loaded, dump, return empty, maneuver, and delay times.

Loader production, assuming 100% availability and/or utilization, can be determined by

$$P_l = \frac{60 \times C_l \times F_f \times F_s}{t_{lc}}$$

where P_l is the loader production rate based on actual active operating time, bank m³/hr (bank cu yd per hr); C_l is the loader rated capacity, m³ (cu yd); F_f is the loader bucket fill factor, decimal; F_s is the material swell factor, decimal; and t_{lc} is the loader total cycle time for load-and-carry in minutes.

Loader production for load-and-carry applications usually is expressed in bank volume.

6.5.7 Dozers

RONALD M. HAYS

TYPES AND APPLICABILITY

Bulldozers, commonly called dozers, are a self-propelled tractor equipped with a front-mounted blade (dozer) or other assembly. Dozers are of two basic types: (1) track or crawler tractor and (2) rubber-tired or wheel tractor. Crawler dozers also may be equipped with a rear-mounted ripper for loosening unconsolidated soil or fragmenting rock. Both crawler and wheel dozers range up to 90 718 kg (200,000 lb) in operating weight. Dozers normally are powered by an on-board diesel engine with crawler and wheel dozers having flywheel power up to 522 kW (700 hp) and 611 kW (820 hp), respectively.

In surface mines, dozers are used for many applications, including:

- Land clearing.
 - Construction and maintenance of access and haulage roads.
 - Benching and preparation of loading area.
 - Cleanup around excavating and/or loading equipment.
 - Relocate electric cable skids.
 - Maintain waste dump by spreading material, pushing material over dump slope, and grading dump area and slopes.
 - Cleanup around dump area.
 - Push material to hopper for loading.
 - Push overburden short distance as a primary method for stripping overburden.
 - Push spoil to contour spoil piles for reclamation.
 - Push load tractor-scrapers.
 - Assist disabled vehicles.
 - Relocate pumps, pipes, conveyors, etc.
 - Rip unconsolidated soil and rock.
 - Construction, maintenance, and cleanup of stockpiles.
- Both crawler and wheel dozers are used for all these applications, except ripping which is accomplished by crawler dozers only.

Crawler dozers usually are used for more difficult operating and ground conditions because of high drawbar pull or pushing force provided by the power train; high coefficient of traction in loose earth, soil, and rock; low ground bearing pressure; and excellent stability. Wheel dozers are advantageous where conditions are more consistent such as dozing uniform material with a high coefficient of traction. With favorable ground conditions, wheel dozers generally provide greater pushing force when operating above speeds of 3.2 to 4.8 km/h (2 or 3 mph) than crawler dozers of the same class. Wheel dozers also are highly mobile and can be moved quickly from one location or application to another. Dozers are versatile and are essential at almost all surface mines.

CRAWLER DOZERS

Drive trains for crawler dozers use high speed diesel engines with power transmitted to tracks through mechanical drives. Drive train configuration varies depending on manufacturer and dozer size. Common drive train components are flywheel clutch to disengage engine and drive train when stopping or shifting gears; torque converter to provide shock-absorbing slippage between engine and track, provide torque multiplication and reduce number of transmission gear ratios, and provide for on-the-move power shifting; manual and power shift transmissions to provide for change in speed-

power ratio and reverse travel; power takeoff to power accessories and hydraulic systems; rear drive assembly to provide final drive gear reduction for power to drive wheels or sprockets and clutches and brakes for steering; drive sprockets to provide positive drive to the tracks; and tracks to support the dozer and provide traction. The dozer undercarriage consists of track frames, drive sprockets, front idlers, rollers, track adjustor, chain links and pins, and track shoes.

The two basic crawler dozer undercarriage designs are shown in Fig. 1. Conventional design has the drive at the rear of the track frames while the newer design has the drive sprockets elevated above and separated from the track frames. The dozer blade is controlled by lift, tilt, and angling hydraulic cylinders. The dozer ripper also is controlled by hydraulic cylinders.

Drive train performance is characterized by a performance curve of drawbar pull vs. velocity such as shown in Fig. 2. Drawbar pull is the horizontal force at the drawbar or the force the drive train can produce at the track-ground contact. Manufacturer's curves must be adjusted for altitude and temperature if different from those specified. The maximum force which can be transferred from the tracks to ground is the product of the coefficient of traction between tracks and ground (see Section 6.5.2, *Trucks*, Table 3) times the normal force on the ground due to the dozer operating weight. Thus, usable force is limited by either this maximum force or drawbar pull.

Fig. 1. Crawler dozer designs. Top: Conventional sprocket design. Bottom: Elevated sprocket design.

Fig. 2. Crawler dozer performance curve, 268-kW (360-hp) engine.

As an example, consider a 268 kW (360 hp) dozer with an operating weight of 41 227 kg (91,000 lb) that is pushing loose gravel with a 0.50 coefficient of traction. Based on the performance curve, the dozer drive train can provide a maximum force or drawbar pull of 63 500 kg (140,000 lb). However, the maximum force which can be transferred from the track to ground is 20 638 kg (45,500 lb).

Important dozer specifications are blade capacity, engine kilowatt (horsepower), machine operating weight including optional equipment, track width and ground contact area, and general dimensions. Dozer ground bearing pressure depends on machine operating weight and track ground contact area. Various width tracks are available for each dozer. A variety of track shoe types are available for special applications.

A pair of crawler tractors may be linked together and operated as a single machine with one operator. The two machines may be linked in-line with a front-to-rear swivel fastener or side-by-side with a rigid tube at the rear and a common blade at the front.

Crawler dozers may be equipped with a power and velocity sensing system which allow the operator to maximize effective dozer work. This system functions by measuring dozer true ground velocity and pushing force. The operator then can vary the blade cutting depth or loading, which alters the velocity and pushing force so that the dozer operates at full power and the most efficient portion of the dozer performance curve.

WHEEL DOZERS

Wheel dozers used in mining applications usually have a center-articulated design as shown in Fig. 3. The engine is at the rear, providing even weight distribution between front and rear axles. The operator's compartment usually is above the pivot point.

Drive trains for wheel or rubber-tired dozers use high speed diesel engines with power transmitted to all four wheels

by mechanical or electric wheel drives. Drive train varies depending upon manufacturer and dozer size with only very large dozers using electrical wheel drives. For mechanical drives, power is transmitted from the engine to all four wheels by a torque converter and transmission, drive shaft and necessary universal joints to front axle and drive shaft to rear axle, front and rear differentials, and final planetary drives. Electric wheel drive dozers use a diesel engine to drive an a-c generator that provides electric current to a solid-state electric power converter. The converter provides d-c current to each electric wheel motor which then drives the final planetary gearing. Because each wheel has its own wheel motor, wheel spin or slippage can be controlled by reducing power as the wheel loses traction.

Drive train performance is characterized by a performance curve of rimpull vs. velocity as shown in Fig. 4. This performance curve is for a mechanical drive dozer and is interpreted in the same manner as the truck performance curve. Manufacturers' performance curves must be adjusted for altitude, temperature, and tire size if different from those specified. These adjustments are the same as made for trucks. As with crawler dozers, usable force is limited by machine traction or rimpull.

Fig. 3. Wheel dozer design.

Fig. 4. Wheel dozer performance curve, 250-kW (335-hp) engine.

Wheel dozers are equipped with service, emergency, and parking brakes. Service brakes may be shoe-drum or disk brakes with air, air-over-hydraulic, or all hydraulic activated. Service brakes provide braking to all four wheels. In addition to shoe-drum or disk brakes, electric wheel drive dozers are equipped with dynamic retarders. With dynamic retarders, the wheel motor becomes a generator with generated energy dissipated as heat by resistors.

For mechanical drive dozers, hydraulic pump(s) are operated by an engine power takeoff. For electric wheel drive dozers, hydraulic pump(s) are driven electrically by current from the a-c generator. Hydraulic systems power steering cylinders and blade lift, tilt, and tip cylinders. Steering of articulated dozers is by hydraulic cylinders which force the front and rear of the machine to pivot around the center hinge.

Traction and stability are improved by free floating axles with a fixed front axle and oscillating rear axle to maintain good tire-ground contact.

Wheel dozers may be operated with either bias ply or radial tires. Dozers use the same tires as wheel front end loaders. The Tire and Rim Association (T&RA) code identifications for loader and dozer tires are:

- L-2 Traction.
- L-3 Rock.
- L-4 Rock deep tread.
- L-5 Rock extra deep tread.
- L-4S Smooth deep tread.
- L-5S Smooth extra deep tread.
- L-5/L-5S Half track extra deep tread.

The L-4 and L-5 tires are most common dozer tires with L-5 tires commonly used for production dozing. Radial tires may have different tire identification codes.

Dozer tires may be filled with liquid or finely powdered mineral ballast to increase machine operating weight. A calcium chloride solution with 75% filling is commonly used for liquid ballast. Protective tire chains may be used for dozers working in abrasive materials. These chains, which cover the tire with chain mesh, provide protection against tire slippage, gouging, cuts, and momentary overloads. Special tires with steel shoes or treads are available to provide complete protection against abrasion and cuts in the tire tread or wear area.

Important wheel dozer specifications are blade capacity, engine kilowatt (horsepower), machine operating weight and distribution including optional equipment, width to outside of tires, wheelbase, tire-ground contact area, turning circle, and general dimensions.

BLADES

A variety of dozer blades as shown in Fig. 5 are available, depending on the application. The blade is a massive structure mounted on the front of the dozer for pushing and controlled by several hydraulic cylinders. The blade may be set straight to push material in front of the dozer or angled to cast material to either side. The blade is attached to the tractor by a push frame which transmits pushing force from the tractor to the blade. The push frame has two push arms attached to each end of the blade. The push frame also may have a V or U-shaped front connector between the push arms with the blade attached at the center of this connector.

The straight or *S* blade is the most versatile blade used for almost all dozer applications. Because the blade has a high cutting edge force per unit of blade width, the *S* blade has good penetration and can handle heavy and tough-to-excavate materials. The small blade width makes dozers with *S* blades easy to maneuver. When equipped with a push plate, the *S* blade is used for push loading scrapers.

The universal or *U* blade has large wings that increase blade capacity. The *U* blade is excellent for pushing big loads over long distances such as in reclamation, stockpile work, charging hoppers, and trapping rock for front-end loaders. This blade also is excellent for spreading fill and finish grading. The *U* blade has relatively poor penetration and is best for lighter and relatively easy to excavate or push materials. Large-capacity *U* blades are available for pushing light non-cohesive materials such as stockpiled coal.

The angling or *A* blade is essentially a straight blade of lower height, more moldboard curvature, and less capacity than the *S* blade. The *A* blade can be angled right or left for side-casting, backfilling, windrowing, benching, and ditching. This blade also can be positioned straight, but usually has less cutting edge force per unit of blade width than the *S* blade. Thus, in the straight position, the *A* blade operates most effectively in light and easy to excavate or push materials.

For relative comparisons, the capacity of straight, universal, and angle blades is calculated in accordance with SAE recommended practice. However, this blade capacity cannot be used satisfactorily to estimate actual blade loading or dozer production.

The cushion or *C* blade is a smaller blade used principally for push-loading scrapers. This blade has rubber cushions to absorb impact when contacting the scraper push block. The narrow blade width increases dozer maneuverability in congested scraper cuts and reduces the possibility of cutting scraper tires. The *C* blade also can be used for scraper cut maintenance and other ground dozing applications.

Many blades have been developed for special applications such as large angle and *U* blades pushed by two side-by-side tractors, narrower and deeper *V* blades, lightweight blades of various designs, bucket-type blades, and straight blades with high sidewalls. The dozer also may be equipped with a special application assembly such as grading bar, tree cutter, rake, etc.

DOZING

When dozers are used for continuous production dozing to push large volumes of material over short distances, pro-

STRAIGHT 'S' BLADE

UNIVERSAL 'U' BLADE

ANGLING 'A' BLADE

CUSHION 'C' BLADE

Fig. 5. Dozer blades.

duction depends on blade loading and dozer cycle time. Production dozing usually is accomplished with a straight or universal blade. When dozers are used for intermittent dozing such as cleanup, benching, haulage road construction and maintenance, etc., production usually is controlled by factors other than blade loading and cycle time.

Blade Loading

The capacity of straight, universal, and angle blades for crawler and wheel dozers are calculated in accordance with SAE recommended practice. Actual blade loading may deviate substantially from blade capacity because of blade design, drive train performance, operating weight, traction, material characteristics, terrain, operating procedure, operator technique, etc.

Three functions performed by the dozer blade are to excavate material using the cutting edge, transport material, and spread material. Dozer drawbar pull and/or operating weight and coefficient of traction between the track or tires and the ground determine the pushing force available for cutting and pushing material. It usually is desirable to operate the dozer near a velocity that maximizes power delivered at the track-ground contact by balancing the cutting depth and blade loading. Cutting depth and material characteristics determine the pushing force required with resistance increasing with increased cutting depth. Consolidated materials that are difficult to cut require a high pushing force in the cut. For single pass dozing of difficult to excavate materials, blade loading often can be maintained by reducing cutting depth to decrease cutting resistance and increasing cut length to increase blade loading. Multiple passes with shallow cutting depth also may be used for difficult to excavate materials. This reduces blade loading, making more pushing force available for cutting material.

Since the load slides or rolls along the ground during transport, friction (internal, blade to material, and material to ground), material density, and blade loading determine the pushing force required for transport. Pushing force requirements are based on experience or field testing. Some dry noncohesive (*dead*) and sticky materials are hard to push. When pushing material downhill, blade loading usually can be increased because gravity is assisting the dozer. Conversely, pushing material uphill decreases blade loading.

Operating procedure such as cutting a slot, operating two blades side by side, or pushing between windrows increase blade loading by reducing side spillage. Operator technique varies considerably. Because of material spillage off the sides of the blade as the dozer transports material, the operator must replace this spilled material to maintain full blade loading.

Blade loading is measured in volume of loose material. Thus, the material swell factor is used to convert from bank volume excavated or material bank bulk density to actual blade loading or material loose bulk density. Actual blade loading can be determined in the field by:

- 1) Counting number of dozer passes, surveying the cut to determine volume of material excavated, and then calculating average blade loading per pass.
- 2) Weighing actual blade load, determining material loose bulk density, and calculating blade loading.
- 3) Measuring actual blade load dimensions and calculating blade loading.

Dozer Cycle Time

Dozer cycle time is the time required for the dozer to complete a full pass including cut, transport, spread, return, fixed, maneuvering, and delay times.

Cut time is the time required to excavate the material in the cut and load the blade. Cut length ranges from 7.6 to 23 m (25 to 75 ft), depending on the dozer and excavating difficulty. Load times usually range from 0.15 to 0.45 min with the longer times for longer cuts with difficult-to-excavate material.

Transport time is the time required to push material from the end of the cut to the beginning of the spread or pile. This time depends on the pushing force required to transport the material. Based on a required pushing force of 13 608 kg (30,000 lb) and the performance curve in Fig. 2, this dozer could transport the load at a velocity of 4.0 km/h (2.6 mph) in second gear. If the transport distance is 61 m (200 ft), the transport time would be 0.87 min.

Spread time is the time required to spread or dump the blade load. Dozers usually spread material while moving forward and raising the blade, spreading a layer of material. Spread times usually range from 0.08 to 0.12 min.

Return time is the time required for the dozer to return backwards to the beginning of the cut. Crawler and wheel dozer return velocities usually are limited to about 8.0 km/h (5 mph) and 16.1 km/h (10 mph), respectively.

Fixed time is the time required for transmission shifting. Maneuvering time is the time required to position the dozer prior to beginning to excavate material. Delay time is due to variable delays such as cut maintenance, driver relief stop, etc.

Total cycle time is the summation of cut, transport, spread, return, fixed, maneuvering, and delay times. The dozer cycle time is greatly affected by operator experience and technique, visibility, terrain, nonuniform ground conditions, and material characteristics.

Dozer Production

Dozer production, assuming 100% availability and/or utilization, can be calculated by

$$P_d = \frac{60 \times L_d \times F_s}{t_{td}}$$

where P_d is the dozer production rate based on actual active operating time, bank m^3/hr (bank cu yd per hr); L_d is the blade loading, loose m^3 (loose cu yd); F_s is the material swell factor, decimal; and t_{td} is the dozer total cycle time in minutes.

Dozer production commonly is in bank volume of material excavated, but the blade loading and volume of material spread, dumped, or piled is in loose volume. Dozer manufacturers can provide graphs, information, and valuable assistance in estimating dozer production.

RIPPING

Crawler dozers can be equipped with a ripper mounted on the rear of the tractor. The ripper shank(s) is pulled through soil or rock to loosen or fragment the material. The material then can be pushed by a dozer or loaded by a front-end loader or scraper.

The rippability of the material is influenced by the material's compressive strength; bedding planes, joints, and fractures; brittleness; and softness and weakness caused by weathering. Glacial tills, shales, sandstones, conglomerates, schists, and coals usually are rippable while massive and homogeneous formations usually are nonrippable. Rippability can be estimated based on seismography testing, which determines the velocity of seismic waves through the material. The seismic wave velocity indicates the degree of material consolidation, including rock strength, stratification

and fracturing, and decomposition. Poorly consolidated materials have lower seismic wave velocity and are easier to rip than hard, tight rock with a higher seismic velocity.

Ripper Types

The three ripper types are radial, parallelogram, and adjustable parallelogram ripper as illustrated in Fig. 6. All three ripper types are raised and lowered by hydraulic cylinder(s). For the radial ripper, the beam pivots to raise and lower the ripper shank(s). Thus, the shank(s) moves in an arc with the shank(s) sloping more forward as the shank(s) is lowered. The parallelogram ripper has upper and lower hinge arms that keep the shank(s) at the same angle to the ground as the shank(s) is lowered. With the adjustable parallelogram ripper, hydraulic cylinders serve as the upper hinge arms. Thus, the shank(s) angle to the ground can be varied to the optimum angle for penetration, either before or during ripping.

The ripper may have a single or multishank arrangement. A single shank, with the digging force applied at a single point, centers the load forces and reduces strain on the tractor and ripper. Multishank rippers with two or more shanks can generate considerable off-center forces when one shank impacts a hard spot or catches or pushes a slab ahead of the shank. For multishank rippers with three shanks, the ripper usually can be operated with all three shanks, the two side shanks, or the center shank only.

The shank may be straight or curved. Straight shanks usually are used for blocky formations while curved shanks are used for bedded or laminated deposits where an uplifting action causes further fragmentation. Each shank is equipped with a detachable point or tip, which can be of various designs with shorter tips providing greater resistance to breakage.

A single center shank with a short tip is usually used for heavy ripping where penetration is difficult and shock is severe. Long tips are used for unconsolidated abrasive materials that are easy to rip. Multishank (two or more shanks) can be used for easily ripped materials.

The ripper can be equipped with a push block so that the ripper can be pushed by a second dozer for very heavy ripping. The second or pushing dozer also can add down pressure to the ripper.

Ripping Technique and Cycle Time

Good penetration, which is essential for high production, depends on the material, down pressure, and point or tip angle to the ground. Ripping usually should be near full depth since shallow ripping is irregular and causes high tip wear. However, ripping to partial depth may be desirable because of limited drawbar pull, traction, or penetration or when natural planes of weakness occur at partial depth. It is important to maintain uniform ripping depth and breakage to minimize difficulty in loading material by scrapers or other equipment.

Ripping direction can affect ripper production. If the material's bedding planes are slightly dipping, ripping should proceed in the direction of the dip so that the bedding planes assist point penetration by pulling the point downward. If the material's bedding planes are steeply dipping, ripping should proceed across or perpendicular to the bedding planes or strike. If ripping depth is irregular or material cannot be fragmented adequately by a single pass, it may be desirable to cross rip the area by making a second pass perpendicular to the first pass. If the surface is sloped, downhill ripping should be used whenever possible.

Ripper production is affected by the spacing between

RADIAL RIPPER

PARALLELOGRAM RIPPER

ADJUSTABLE PARALLELOGRAM RIPPER

Fig. 6. Ripper types.

ripper passes. Wide spacing increases production, but may result in irregular ripping depth or poor fragmentation. Thus, spacing must be close enough to insure a uniform ripping depth and fragmentation fine enough for loading, haulage, and possibly crushing without major difficulties.

When ripping, the tractor usually is operated in first gear at velocities of 1.6 to 2.4 km/h (1 to 1.5 mph), including slippage and stalls. Higher velocities tend to increase wear on both tractor undercarriage and ripper shank(s) and point(s).

The ripper cycle time consists of rip, turn, and delay times. Rip time is the time required to make a single pass while ripping and is based on the rip distance and average dozer speed. Turn time is time required to turn the tractor and maneuver to begin the next pass. Turn time usually is 0.20 to 0.35 min. Delay time is time for variable delays. Ripper total cycle time is the summation of rip, turn, and delay times.

Ripper Production

Ripper production depends on the material's rippability, the tractor and ripper, ripping technique and procedure, and operator experience and ability.

Since ripper production depends on many factors that cannot be quantified, reliable methods of estimating production depend on field studies. The two principal methods are to:

1. Determine average cycle time; measure average rip distance, rip spacing, and depth of penetration; calculate volume of material ripped; and then calculate production rate.
2. Record time spent ripping, remove and weigh ripped material or survey the area after removal of ripped material and calculate volume of ripped material, and then calculate production rate.

Ripper production rate is usually in bank volume or bank m^3/hr (bank cu yd per hr). Based on ripper cycle time, ripper production, assuming 100% utilization and/or availability, can be calculated by

$$P_r = \frac{60 \times L \times w \times p}{t_r}$$

where P_r is the ripper production rate based on actual active operating time, bank m^3/hr (bank cu yd per hr); L is the rip distance (length of ripped area), m (yd); w is the rip spacing (distance between ripper passes), m (yd); p is the depth of penetration, m (yd); and t_r is the ripper total cycle time in minutes.

As an example, consider a 58 967 kg (130,000 lb) dozer with a single shank ripper that rips at an average velocity of 1.6 km/h (1 mph), turn time of 0.30 min, delay time of 0.50 min, 152 m (167 yd or 500 ft) rip distance, 0.914 m (1 yd or 3 ft) rip spacing, and 0.610 m (0.67 yd or 24 in.) depth of penetration. Rip time then is 5.68 min for a total cycle time of 6.16 min. Ripper production rate is 851 bank m^3/h (1113 bank cu yd per hr). This production rate does not include any idle time, fixed delays, or downtime for preventive maintenance.

COSTS

Ownership costs for dozers and rippers are determined in the same manner as for other mobile equipment and include depreciation, interest, insurance, and taxes. Delivered cost includes factory cost of tractor; blade, ripper and any optional equipment; freight; and erection at the mine. For crawler dozers, depreciable value is the same as delivered

cost. However, for rubber-tired dozers, the cost of tires is deducted from delivered cost to obtain depreciable value. For crawler tractors operating at mines, useful life ranges from about 8000 to 18,000 hr depending on the specific dozer, application, and operating conditions. Ripping consolidated rock is one of the severest applications for a crawler tractor. For wheel dozers, useful life ranges from about 8000 to 12,000 hr for mining applications. Table 1 shows ownership costs for both a crawler and a wheel dozer.

Operating costs for crawler dozers include fuel, preventive maintenance, undercarriage and track maintenance, mechanical repairs, blade cutting edge replacement, ripper shank and point replacement, and operator wages. Wheel dozers have operating costs for tires and tire repair but do not have costs for undercarriage and track maintenance.

Hourly fuel consumption and cost can be calculated by the same method used for other mobile equipment. Table 2 presents crawler and wheel dozer engine load factors for light, average, and heavy applications. Preventive maintenance cost, including lubricating oils, greases, filters, hy-

draulic oils, miscellaneous parts, and labor, is about 20% of fuel cost. A more detailed estimate can be made on specific machine data and local costs.

For crawler dozers, operating cost for undercarriage and track maintenance and repair may represent a major operating cost. This cost is difficult to estimate and highly variable, depending on operating conditions and procedures and maintenance practices. Nonpenetrable consolidated materials and hard rough surfaces increase undercarriage and track maintenance cost because of high impact loadings that cause bending, chipping, cracking, and spalling of contact surfaces and increased stress on pins and bushings. Abrasive materials, such as wet soils with a high proportion of hard, angular, or sharp particles, increase wear on undercarriage and track wear surfaces and components. Earth that packs in sprocket teeth, corrosive chemicals, and excessive soil moisture increase cost. Terrain requiring sidehill work will increase component wear. Operating procedures such as high-speed backing, tight turns, and track slippage will increase undercarriage and track maintenance cost. Maintenance

Table 1. Crawler and Wheel Dozer Ownership and Operating Costs

Dozer Type	Crawler		Wheel	
Shipping weight, kg (lb)	41,277 (91,000)		32,659 (72,000)	
Rated brake power, kW (hp)	268 (360)		250 (335)	
Capital cost				
Standard dozer, fob factory	\$284,000		\$244,500	
Optional equipment, fob factory	28,500		11,750	
Freight (5.7¢/lb)	5,200		4,100	
Erection	2,000		1,500	
Delivered cost	\$319,700		\$261,850	
Tires	—		19,700	
Depreciable value	\$319,700		\$242,150	
Dozer life				
Years	3		2	
Hours	15,000		10,000	
Average annual investment	\$213,133		\$181,613	
	\$/hr	\$/yr	\$/hr	\$/yr
Ownership costs				
Depreciation	21.31	106,567	24.22	121,075
Interest (15% of average annual investment)	6.39	31,970	5.44	27,242
Insurance (2% of average annual investment)	0.85	4,263	0.73	3,632
Taxes (2% of average annual investment)	0.85	4,263	0.73	3,632
Total ownership costs	29.40	147,063	31.12	155,581
Operating costs				
Fuel (0.60 load factor)				
43.9 L/hr at \$0.330/L				
(11.6 gal/hr at \$1.25/gal)	14.50	72,500		
40.9 L/hr at \$0.330/L				
(10.8 gal/hr at \$1.25/gal)			13.50	67,500
Preventive maintenance				
(0.20 × fuel cost)	2.90	14,500	2.70	13,500
Tires and tire repair (2000 hr)				
(\$19,700/2000 hr) × 1.15	—	—	11.33	56,640
Undercarriage and track maintenance	13.00	65,000	—	—
Repair				
(\$319,700/10,000) × 0.32	10.23	51,152		
(\$242,150/10,000) × 0.30			7.26	36,323
Wear items	3.75	18,750	2.80	14,000
Operator	20.00	100,000	20.00	100,000
Total operating costs	64.38	321,902	57.59	287,963
Total ownership and operating costs	93.78	468,965	88.71	443,544

Table 2. Dozer Engine Load Factor

Dozer Type	Load Factor*		
	Light	Average	Heavy
Crawler	0.45	0.60	0.75
Wheel	0.45	0.60	0.80

* *Light*: Considerable idle or travel with no load.

Average: Normal idle, normal production dozing, back track push loading scrapers, steady shovel cleanup.

Heavy: Minimum idle and reverse travel, heavy production dozing, chain and shuttle push loading scrapers, steady ripping.

Table 3. Dozer Repair Factor

Dozer Type	Repair Factor*		
	Light	Average	Heavy
Crawler	0.16	0.32	0.50
Wheel	0.20	0.30	0.40

* Based on 0-18,000 hr crawler dozer life and 0-12,000 hr wheel dozer life.

practices with periodic wear measurements and servicing reduce undercarriage and track maintenance cost.

For wheel dozers, tire life is influenced by operating conditions and procedures, as well as tire construction, type, loads, and maintenance. Typical life of L-3 bias ply tires is 1500 to 2500 hr with tire life being extended by L-4 and L-5 tires. Tire life is shortened by tire spinning. When dozing rock, excessive wear and rock cuts, rips, and punctures can shorten tire life. Hourly tire and tire repair cost is 115% of hourly tire replacement cost.

Hourly repair cost can be calculated by the same method used for other mobile equipment. Table 3 presents repair factors for crawler and wheel dozers. The depreciable value used to determine the repair cost must be a current value to reflect current repair cost.

The cost of replacing and welding blade-cutting edges, ripper shank and points, and other high-wear items varies widely depending on materials, applications, and operator experience. Operator wages normally include base wage, fringe benefits, training, and other related costs.

Dozer and ripper production costs usually are presented as cost per bank cubic meter (cubic yard). For dozing, this production cost does not consider the distance the material is transported.

6.5.8 Haulage Systems Simulation Analysis

R. V. RAMANI

INTRODUCTION

In a mining operation, the haulage system is the intermediate component between the loading and the dumping systems. Together, the three form the materials handling system. Materials handling systems are characterized by a combination of inventory, waiting line, allocation, and replacement processes. Effective and efficient haulage systems can only be developed through a detailed consideration of these processes in a systems analysis framework. Otherwise, overloads and production bottlenecks will result at unexpected places in the mining system. The term *systems analysis* is used here to describe an integrated approach which views an entire system of components as an entity rather than as an assemblage of parts, i.e., a system in which each component is designed to fit properly with other components rather than to function by itself.

In surface mines, the transport of material from production faces to dumping sites is accomplished by rail, truck, belt conveyor, hydraulic transport or skips. In a systems analysis model of this haulage system, to provide both continuity and completeness, it is common to include the two most important interconnected systems—the loading system and the dumping system. Some of the earliest applications of computers in surface mining were in the materials handling system (Ware, 1955; Dunlop and Jacobs, 1955). Manufacturers of locomotives, trucks, and belt equipment use computer simulation programs to predict the performance of the haulage equipment over given haul profiles. Since shovel-truck systems are most common in open pit mining, many computer models have been developed to study these systems. In view of its importance and relevance to the analysis of haulage systems, this section on simulation covers broadly, with numerical examples, a range of topics in the areas of modeling, probability distributions, Monte Carlo sampling, deterministic and probabilistic simulation, and simulation models.

MATHEMATICAL MODELLING

In industrial and business settings, decision-making is constrained by many external factors, such as competition and the market, over which there may be little or no control. On the other hand, there is a high degree of selectivity with regard to internal factors such as methods of operation, equipment, and management. For example, in the selection of a haulage system for a surface mine, the location of the ore body, the ore grade and mineralization, though important, cannot be varied. However, there is considerable flexibility in the selection of the haulage method (trains, trucks, belts, pipelines, etc.), in the choice of equipment for the haulage method (small, large, bottom dump, side dump, etc.), and in the location of the mine facilities (dumps, ore pockets, bins, etc.). The objective of decision-making, in the systems analysis framework, is to select from the entire set of controllable and noncontrollable factors, those combinations of controllable factors which contribute most to the overall growth of the company. Symbolically, the problem can be represented as:

Optimize $Z = F(X_i, Y_j) \quad i = 1, 2, \dots, M; j = 1, 2, \dots, N$

where

Z = Measure of effectiveness (cost, profit, production, etc.)

X_i = Controllable variables

Y_j = Noncontrollable variables

F = Functional operator.

This symbolic model outlines the essentials of the systems approach to decision-making. First, the controllable and uncontrollable variables of the system must be identified; second, the measure of effectiveness of the decision-maker must be defined, third, the scale for the measure of effectiveness must be established, and fourth, the relationships between the controllable and uncontrollable variables must be functionally defined. And finally, the solution (or the result) of the functional relationships must be integrated into a measurement on the effectiveness scale to serve as an indication of the value of the outcome of a particular decision.

The simplicity of the symbolic model belies the complexity of the real world decision-making environment. There are aspects of a decision-making environment, particularly, the sociohumanistic aspects, which may not be easily modeled. In practice, the measure of effectiveness is rarely single-valued. Problems are encountered in defining the boundaries of the system being analyzed. Often, it is not possible to solve the functional relationships using classical methods of mathematics.

SYSTEMS SIMULATION

Mathematical models have been classified as linear or nonlinear; stable or unstable; steady-state or transient; open or closed; and deterministic or stochastic (Forrester, 1961). Unstable, unconstrained models lead to explosive oscillations and are not representative of real-world systems. The model development may be based on theoretical knowledge of the system or on the analysis of data from the system. In the latter method, the values for many system variables are recorded under different operating conditions and empirical relationships between input and output variables are determined through the use of statistical techniques. The model development may also use various combinations of theoretical knowledge and empirical findings. There is an arsenal of tools and techniques and approaches to develop a model of a system.

Mathematical models of complex systems are difficult not only to develop but also to solve. For a particular haulage system study, assuming the loading and dumping systems are fixed along with the production rate, Z can be defined as the total haulage cost, X_i as the controllable variables of a haulage system (the type of haulage system, the size and number of haulage equipment, haul road profile and conditions, etc.) and Y_j , the uncontrollable variables (the desired production and the loading and dumping systems and their characteristics and locations). As stated here, the decision-maker is interested in minimizing the haulage cost for a defined production through the best choice of the type of haulage system and the size and number of equipment for the chosen system. Related objectives include minimizing

waiting times and maximizing utilization of all equipment on a priority basis.

In surface mining the complex interdependence between the variables in the haulage system and the dynamic interactions between the haulage system and other related systems make a haulage system model too intricate to develop with classical tools and techniques. Specifically, in a shovel-truck haulage system, the loading time of a truck and the load (amount of material) on a truck are statistical variables. The performance of the truck on a haul road is a function of the truck speed-rimpull curve, the haul road profile and conditions, and the load on the truck. The truck travel times are also a function of the number and types of trucks on the haul road. Thus, a model of the shovel-truck system must have static, dynamic, kinematic, and statistical elements. In these instances, a systematic approach to improve on intuition and experience is to build a *simulation model* of the system. System simulation is defined as the technique of solving problems by following changes over time on a dynamic model of the system. Simulation models can be discrete, continuous, or a combination of both, in the dimensions of time and variables' value (Emshoff and Sisson, 1970; Gordon, 1969). The technique does not attempt to solve the equations of a model; rather it observes the way in which the controllable variables of the model change with time. While dynamic *physical* models can be useful for simulation studies, the model in most cases, is a computer program in which the theoretical knowledge and empirical findings about the system are incorporated. The inputs to the program consist of the values of the controllable and noncontrollable variables. The outputs of the program are measures of performance or cost. There is usually no explicit optimization in simulation. The best solution is found by conducting a number of experiments, the inputs to each of which are developed on the basis of the results of prior simulations, intuition, and experience. In essence, simulation is an experimental problem-solving technique.

The simulation approach is applicable to systems where classical analytical techniques are not feasible. There are no precise guidelines as to how to simulate a system. These two attributes—general applicability and lack of guidelines—have given simulation great flexibility and wide use, but because of these attributes, there also is a possibility for misapplication and abuse. Therefore, model builders must ensure that the simulation model of a system is in fact a valid representation of reality.

Three points are worth noting at this stage. First, the objective of modeling is to create abstractions of reality on which experiments can be performed to understand reality. Therefore, attempts to develop models that duplicate reality in *all* aspects may not be very useful or possible. In very detailed models, variations of outputs may not be tractable to changes in inputs, i.e., the cause and effect relationship may not be clearly established to enable decision-making. The objective should be to capture the *essence* of the real world system. Second, no model, however detailed and allegedly related to a system for which it is a model, can explain all observations. In the acceptance or rejection of a model for use, therefore, there should always be an element of judgment. Third, data is necessary for the development and application of any model. One should not, however, demand that data gathering be a prerequisite to model building. Some systems may require model building first and the data collection later. It is difficult to establish the sufficiency of data and, in this respect, the data needs of each system must be evaluated individually.

The concepts presented here are illustrated in a number of models—deterministic, statistical, and simulation—that are developed in subsequent sections.

CYCLE TIME MODEL

The cycle time for a haul unit can be expressed as (Su-boleski, 1975):

$$LCT = STL + LT + TL + STD + DT + TE + AD \quad (1)$$

where:

LCT = cycle time of a haul unit, min

STL = spot time at the loader, min

LT = load time of the haul unit, min

TL = travel time (loaded), min

STD = spot time at the dump, min

DT = dump time, min

TE = travel time (empty), min

AD = average delay on the haul cycle, min (wait at dump, wait at the loader, or slow down on the haul road).

Also,

$$LT = \frac{TCP}{LR} \quad (2)$$

where:

TCP = capacity of the haul unit, short tons*

LR = loading rate of the loader, st/min

With shovel-truck systems,

$$LT = \left[\frac{TCP}{BCP} \right]^* \times CTL \quad (3)$$

where:

BCP = bucket capacity of the loader, st (adjusted for fill factor, etc.)

CTL = cycle time of the loader, min (adjusted for loading efficiency, etc.)

[*] implies that the value is rounded up to the next higher integer.

$$TL = \frac{HD}{SL} \quad (4)$$

$$TE = \frac{HD}{SE} \quad (5)$$

where:

HD = haul distance from the loader to the dump, ft

SL = speed of a loaded haul unit, ft/min.

SE = speed of an empty haul unit, ft/min.

The value of AD can be determined from time study data. It can also be calculated from an analysis of the system.

Assuming that there is no delay at the dump or the haul road, the number of haul units required to keep the loading unit busy is given by:

$$N = \left[\frac{LCT}{STL + LT} \right]^* \quad (6)$$

where [*] implies that the value is rounded up to the next higher integer.

* Metric equivalents: st \times 0.907 184 7 = t; ft \times 0.3048 = m; mph \times 1.609 = km/h.

Example 1

Consider the following case:

$$BCP = 5 \text{ st}$$

$$CTL = 0.5 \text{ min}$$

$$STL = 0.20 \text{ min}$$

$$STD = 0.15 \text{ min}$$

$$DT = 0.35 \text{ min}$$

$$TCP = 27.5 \text{ st}$$

$$HD = 5,000 \text{ ft}$$

$$SL = 2,000 \text{ ft/min (22.73 mph)}$$

$$SE = 2,500 \text{ ft/min (28.41 mph)}$$

$$LT = \left[\frac{TCP}{BCP} \right]^* [CTL] = \left[\frac{27.5}{5} \right]^* [0.5] = 6 \times 0.5 = 3.0 \text{ min}$$

$$TL = \frac{5,000}{2,000} = 2.5 \text{ min}$$

$$TE = \frac{5,000}{2,500} = 2.0 \text{ min}$$

$$LCT = (0.20 + 3.0 + 2.5 + 0.15 + 0.35 + 2.0) \text{ min} = 8.20 \text{ min.}$$

In the above example, the haul unit is at the loader for 3.20 min ($STL + LT$), i.e., another haul unit cannot spot, till the loaded haul unit pulls away from the loader.

$$N = \left[\frac{LCT}{STL + LT} \right]^* = \left[\frac{8.20}{0.20 + 3.0} \right]^* = [2.56]^* = 3$$

Two haul units will keep the loader waiting for the haul unit to arrive from the dump. The average wait time of the loader, for every other haul unit, will be $(2.56 - 2)(3.2) = 1.80$ min. With three haul units, each truck will wait for $(3 - 2.56)(3.2) = 1.41$ min at the loader before the loader starts loading it. These are easily explained by drawing a simple Gantt chart of the status of the loading and hauling units as a function of time. Fig. 1 shows the Gantt chart for a loader with two and three haul units. Equating the loader and haul unit times for the interval I in Fig. 1 for the two haul units case, the waiting time (W) of a unit can be calculated:

$$\begin{aligned} 2(STL + LT) + W &= STL + LT + TL \\ &\quad + STD + DT + TE \quad (7) \\ W &= (TL + STD + DT + TE) \\ &\quad - (STL + LT) \end{aligned}$$

For the two haul unit cases, the total wait time (TW) for n haul cycles is

$$TW = \left(\frac{n-1}{2} \right) \{ [TL + STD + DT + TE] - [STL + LT] \} \quad (8)$$

These equations can be generalized for N haul units as follows:

$$W = [TL + STD + DT + TE] - (N-1)[STL + LT] \quad (9)$$

$$TW = \left[\frac{n-1}{N} \right] \{ [TL + STD + DT + TE] - (N-1)[STL + LT] \} \quad (10)$$

By increasing N , W can be decreased. If N is sufficiently large, then W can become negative. A negative W implies that the first haul unit completes its cycle before all other haul units have been loaded.

For the example under consideration, with only one haul unit, it is clear that the loader will wait for 5.20 min between trips. With two haul units,

$$W = [2.5 + 0.15 + 0.35 + 2.0] - [0.2 + 3.0] = 1.8 \text{ min.}$$

i.e., the loading unit will be waiting 1.8 min every other trip. This is shown in the Gantt chart. With three haul units,

$$W = [2.5 + 0.15 + 0.35 + 2.0] - 2[0.2 + 3.0] = 5.0 - 6.4 = -1.4 \text{ min.}$$

$W = -1.4$ implies that each truck waits for 1.4 min at the loader every trip. This is also clear from the Gantt chart.

Example 2

In the above problem, the one-way haul distance increases to a maximum of 4572 m (15,000 ft). Calculate the number of hauling units required as a function of the haul distance such that the shovel waiting time is zero.

Let N = number of haul units

$$W = [TL + STD + DT + TE] - [N-1][STL + LT]$$

$$\begin{aligned} W &= \left[\frac{HD}{2000} + 0.15 + 0.35 + \frac{HD}{2500} \right] - [N-1][0.2 + 3.0] \\ &= \left[\frac{2.5 HD + 2 HD}{5000} + 0.5 \right] - 3.20 N + 3.20 \\ &= \frac{4.5 HD}{5000} - 3.20 N + 3.7 \end{aligned}$$

Fig. 1. Gantt chart.

Condition for loader wait time to be zero or lower is given by

$$W = \frac{4.5 HD}{5000} - 3.20 N + 3.7 \leq 0$$

or

$$N \geq \frac{4.5 HD}{16000} + 1.16$$

$$N \geq 0.00028 [HD] + 1.16$$

For: $HD = 5000$ ft	$N > 2.56$	$N = 3$
$HD = 7500$ ft	$N > 3.26$	$N = 4$
$HD = 10000$ ft	$N > 3.96$	$N = 4$
$HD = 12500$ ft	$N > 4.66$	$N = 5$
$HD = 15000$ ft	$N > 5.36$	$N = 6$

The shift production is a complex function of many factors such as the number of loading units, the number of haul units, the number of dumps, availability of these units, the haul road length and hauling speeds. The total performance of the mining system is the result of the interaction between all these factors. Deterministic calculations as previously presented are useful for preliminary evaluation. On the other hand, the various elemental times in a cycle can be and often are random variables. Therefore, whenever data is available, application of statistical techniques provides better answers.

TRUCK FLEET SIZING

One of the important criteria in surface mine equipment selection is the determination of the truck fleet size. It is common to establish the total fleet size as:

$$\text{Total fleet size} = \frac{\text{number of trucks required in operation}}{\text{availability of a truck}} \quad (11)$$

$$\text{Availability} = \frac{\text{possible hours-downtime hours}}{\text{possible hours}} \quad (12)$$

For example, if 16 trucks are required to meet the production, and the availability of a truck is 0.8, then the total fleet size is calculated as $(16/0.8) = 20$. Twenty trucks in the fleet are inadequate to meet the operational requirements of 16 trucks. A better way to calculate the truck fleet size using a binomial distribution is presented by Connel (1969, 1973). Defining:

P_n = probability that exactly n units are available

P_a = probability that a single unit is available

P_{na} = probability that a single unit is not available = $(1 - P_a)$

N = total number of units in the system

Nc_n = combination of N things, taken n at a time ($n \leq N$).

$$P_n = Nc_n (P_a)^n (P_{na})^{N-n} \quad (13)$$

Also,

$$P_{1n} = \sum_{x=n}^N Nc_x (P_a)^x (P_{na})^{N-x} \quad (14)$$

where P_{1n} = probability at least n units will be available. As N and n increase, it is preferable to use a computer program to calculate these probabilities.

Example 3

Given that the availability of a single truck is 0.8, and that the truck fleet size is 20, calculate (1) the probability

that exactly 16 trucks will be available, and (2) probability that at least 16 trucks will be available.

Note: $N = 20$, $n = 16$, $P_a = 0.8$, $P_{na} = 0.2$

$$P_{16} = 20c_{16} (0.8)^{16} (0.2)^{20-16} = 0.2182$$

$$\begin{aligned} P_{116} &= P(n \geq 16) = P_{16} + P_{17} + P_{18} + P_{19} + P_{20} \\ &= 0.2182 + 0.2054 + 0.1369 + 0.0576 + 0.0115 \\ &= 0.6296. \end{aligned}$$

Thus, with a fleet size of 20, there is only a 62.96% chance that at least 16 trucks will be available. In other words, there is a 37.04% chance that less than 16 trucks will be available. This is too high a probability for having a lower number of trucks than required for maintaining production. This probability should not normally exceed five to ten percent.

Example 4

For the data in Example 3, calculate the truck fleet size to ensure that there is at least a 95% probability of having 16 units available. Let N = truck fleet size. It is required that $P_{116} > 0.95$.

$$P_{116} = \sum_{x=16}^N Nc_x (P_a)^x (P_{na})^{N-x}$$

$$\text{i.e., } \sum_{x=16}^N Nc_x (P_a)^x (P_{na})^{N-x} > 0.95$$

In the previous inequality, solve for the value of N by trial and error. The values of P_{116} for various values of N are as follows:

N	P_{116}
22	0.8670
23	0.9285
24	0.9638
25	0.9827
26	0.9921

A fleet size of 24 trucks will be inadequate.

The fleet size can be decreased by increasing the availability of the individual truck. This may be possible by such measures as buying better trucks, improving maintenance, and reducing avoidable delays. An alternate approach, though not recommended, is to allow a higher probability for not having the required number of trucks in operation.

Example 5

There are three types of trucks with availabilities of 0.8, 0.85, and 0.90, respectively. Calculate the fleet size required for each truck type to ensure that there are 90, 95, and 99% chances of having 16 trucks in operation.

Solution

There are nine cases to be evaluated: three truck types \times three different probabilities for 16-truck operation.

Number of trucks needed in the fleet
for 16-truck operation

Truck availability	90% of the time	95% of the time	99% of the time
0.8	23	24	26
0.85	21	22	24
0.90	19	20	21

Thus, the fleet size is variable depending on the truck availability and the desired probability for having the required number of trucks. The justification to select the appropriate truck type and the fleet size can be made only after a thorough cost analysis.

MONTE CARLO SAMPLING

A useful application of probability and statistics involves sampling by the Monte Carlo method. For example, the loading time of a haul unit including spotting time may be exponentially distributed. The dumping time including spotting time, on the other hand, may be uniformly distributed. The travel times for the loaded and empty trip may be normally distributed. The truck cycle time, therefore, is the sum of four random variables. Through Monte Carlo simulation, truck cycle times can be generated. For applying the Monte Carlo technique, one proceeds as follows (Sasieni, Yaspan, and Freidman, 1959):

1. Calculate the cumulative probability function $F(x)$ of the variable x over its range (see Fig. 2):

$$y = F(x) = \int_{-\infty}^x f(x) dx$$

where $f(x)$ is the frequency density function of x .

2. Choose a random number, r , between 0 and 1 from a table of random numbers (for example, see Table 1).

3. From the cumulative probability function $F(x)$, find the value of x corresponding to $y = r$.

This simulated value of x is distributed according to the frequency density function of the variable x . It is clear from the figure that the probability of having a simulated value between x_1 and $x_1 + dx$ is proportional to $f(x_1)dx$.

$$P(x_1 < \text{simulated value} < x_1 + dx) = dy_1 = f(x_1)dx$$

In the event the variable is discrete, then $F(x) = \sum_{u=0}^x f(u)$.

Example 6

The cycle time of a haul unit follows the density function:

$$f(t) = \frac{1}{20} (t + 3) \quad 6 \leq t \leq 8$$

$$f(t) = 0 \quad \text{elsewhere}$$

where t = cycle time of truck in minutes. Generate the average of ten cycle times by the Monte Carlo technique. Compare this average with the average of the distribution.

Solution

$$F(t) = \int_6^t f(t) dt$$

$$= \frac{1}{20} \int_6^t (t + 3) dt$$

$$= \frac{1}{20} \left[\frac{t^2}{2} + 3t - 36 \right] \quad 6 \leq t \leq 8$$

Calculating the value of $F(t)$ for values of $t = 6, 6.5, 7, 7.5$, and 8, the following results are obtained: $F(6) = 0.0$, $F(6.5) = 0.23$, $F(7) = 0.48$, $F(7.5) = 0.73$, $F(8) = 1.0$.

The cumulative probability function is plotted in Fig. 3. Choosing ten random numbers from the random number table, the cumulative distribution is sampled with the following results (see box marked A in Table 1).

Fig. 2. Monte Carlo sampling procedure and justification.

Random number	Truck time, t
10097	6.20
37542	6.75
08422	6.18
99019	8.00
12807	6.25
66065	7.30
31060	6.60
85269	7.70
63573	7.25
73796	7.50

69.73 average = 6.973 min

The theoretical average cycle time is obtained as follows:

$$\mu_t = \int_6^8 t f(t) dt = 7.03 \text{ min}$$

The variance of the cycle time can be calculated from:

$$\sigma_t^2 = \int_6^8 (t - 7.03)^2 f(t) dt$$

If the Monte Carlo sampling procedure were carried to a greater number of samples, then the average of the samples will approach the theoretical average.

The application of the Monte Carlo technique to distributions frequently used in mine simulation studies is summarized in Table 2 (after Taylor, et al., 1966). It is fairly easy to write computer programs to generate random numbers that are distributed according to some distributions. Tables of random numbers distributed normally with $\mu = 0$ and $\sigma^2 = 1.0$ simplify the generation of normally distributed random values:

$$X_N = \mu_N + R_N \cdot \sigma_N$$

where X_N = normally distributed variable with mean, μ_N and variance, σ_N^2 ;

R_N = a number from a table of normalized random deviations (Table 3, see the box marked A).

Example 7

The load on a 109-t (120-st) coal truck is normally distributed with a mean of 190 t (120 st) and a standard deviation of 9 t (10 st). The mine production on a particular day is reported as 20 trucks. Using the table of random numbers, estimate the tons produced.

$$\text{The load on a truck} = 120 + R_{Ni}(5)$$

$$\begin{aligned} \text{The load on 20 trucks} &= \sum_{i=1}^{20} [120 + R_{Ni}(5)] \\ &= 20 \times 120 + 5 \sum_{i=1}^{20} R_{Ni} \end{aligned}$$

Fig. 3. Cumulative probability function for $F(t)$ in example 6.

Choose 20 consecutive random numbers from the table of normalized random deviations (Table 3).

$$\begin{aligned}\text{The load on 20 trucks} &= 20 \times 120 + 10 [-7.625] \\ &= 2400 - 76.3 = 2323.7 \text{ st}\end{aligned}$$

$$\text{Average load per truck} = \frac{2323.7}{20} = 116.9 \text{ st}$$

Depending on the choice of the 20 random normal numbers, the total production and average production per truck will be different. For example, choosing the numbers in the box marked B in Table 3, the answers for the load on 20 trucks and average load per truck are 2476.50 and 123.8 st, respectively.

After data is collected on various variables of interest, it is necessary to analyze and fit the data, if appropriate, to some known distribution. Simulation of haulage systems can be considerably simplified if the time study data can be fitted to standard probability distributions.

A measure of the discrepancy between the observed and expected frequency is supplied by the χ^2 statistic defined as

$$\chi^2 = \sum_{i=1}^n \frac{(o_i - e_i)^2}{e_i}$$

where

o_i = observed number of observations in a cell

e_i = expected numbers of observations in a cell

n = number of cells with more than 5 expected observations

Table 2. Generation of Random Variables According to An Underlying Distribution

Distribution	Parameters	Mean	Variance	x is distributed according to the distribution in column 1. r = uniform random number	Comments
Uniform distribution					
$f(x) = \frac{1}{b-a}$ $a < x < b$, = 0 elsewhere	a, b	$\frac{a+b}{2}$	$\frac{(b-a)^2}{12}$	$x = a + (b-a)r$	$0 \leq r \leq 1$
Exponential distribution					
$f(x) = \alpha e^{-\alpha x}$ $\alpha > 0, x \geq 0$	α	$\frac{1}{\alpha}$	$\frac{1}{\alpha^2}$	$x = -\frac{1}{\alpha} \ln r$	$0 \leq r \leq 1$
Normal distribution					
$f(x) = \frac{1}{\sigma_x \sqrt{2\pi}} e^{-\frac{1}{2} \left(\frac{x - \mu_x}{\sigma_x} \right)^2}$ $-\infty < x < \infty$	μ_x, σ_x	μ_x	σ_x^2	$x = \mu_x + \sigma_x \left[\sum_{i=1}^{12} r_i - 6 \right]$	See note 1 $0 \leq r_i \leq 1$
Binominal distribution					
$f(x) = n_c p x (1-p)^{n-x}$	n, p	np	$np(1-p)$	$r_i \leq p, x_i = x_{i-1} + 1$ $r_i \geq p, x_i = x_{i-1}$ $x_0 = 0$	See note 2 $0 \leq r_i \leq 1$
$x = 0, 1, 2, \dots, n$ $P \geq 0, P \leq 1.0$ (P = Probability of success)					
Poisson distribution					
$f(x) = \frac{e^{-\lambda} \lambda^x}{x!}$	λ	λ	λ	$t_i = -\ln r_i$	See note 3 $0 \leq r_i \leq 1$
$x = 0, 1, 2, \dots$ $\lambda \geq 0$				$\sum_{i=0}^x t_i \leq \lambda \leq \sum_{i=0}^{x+1} t_i$	

Note 1: Twelve random numbers, r_i ($i = 1, 2, \dots, 12$) are generated and used to calculate the value of x .

Note 2: There are n trials conducted. x_0 is initialized to 0. For each trial, a random value r_i is calculated as shown. At the end of n trials, the value of x_n is binomially distributed.

Note 3: A number of trials $i = 0, 1, 2, \dots$ are conducted. For each trial, a random value r is generated and the value of t is calculated. When the stated relationship is satisfied at some $i = x$, then x is poisson distributed.

Source: From tables of the RAND Corp., by permission.

The degrees of freedom of the test is given by $(n - 1 - k)$ where k is the number of parameters of the distribution estimated from the data.

Example 8

Time study data on the dumping time of a 29-t (32-st) truck is analyzed and grouped as follows (O'Neil, 1966):

Dumping time interval, min	Number of observations
0.545 - 0.745	27
0.745 - 0.945	11
0.945 - 1.145	4
1.145 - 1.345	1
1.345 - 1.545	1

Develop an appropriate frequency distribution for the dumping times.

Solution

The histogram of the observed values is plotted (Fig. 4).

Mean of the samples: 0.74

Standard deviation of the samples: 0.16.

From the histogram, it appears that the dumping times are distributed according to an exponential distribution.

The exponential distribution is of the form

$$F(x) = \alpha e^{-\alpha x} \quad \alpha > 0, x > 0$$

Fig. 4. Histogram for data in example 8.

where $\frac{1}{\alpha}$ = mean of the exponential distribution, μ_x . To consider the lower limit of the distribution as zero, the data is translated by subtracting 0.545 min from each observation.

Mean of the translated data = 0.195

$$\alpha = \frac{1}{\mu_x} = \frac{1}{\bar{x}} = \frac{1}{0.195} = 5.13$$

The observed and theoretical frequencies are calculated in Table 4.

Chi-Square Goodness of Fit

$$\begin{aligned} \chi^2 (1 df) &= \sum_{i=1}^n \frac{(o_i - e_i)^2}{e_i} = \frac{(27 - 28.6)^2}{28.6} \\ &+ \frac{(11 - 10.12)^2}{10.12} + \frac{(6 - 5.28)^2}{5.28} \\ &= 0.09 + 0.08 + 0.10 = 0.27 \end{aligned}$$

From tables $\chi^2_{0.95} (1 df) = 3.84$ $\chi^2_{0.05} (1 df) = 0.0039$

At 90% confidence level, it is concluded that the dumping times are exponentially distributed. In a simulation run the dumping time of a 29-t (32-st) truck will be calculated as:

$$DT = 0.545 - \frac{1}{0.195} \log r$$

where r = a random number in the interval (0, 1).

Example 9

Time study data on truck loading times of a 29-t (32-st) truck is analyzed and grouped as follows:

Load time interval, sec	Mid-point, sec x_i	Number of observations, f_i
60 - 62	61	5
63 - 65	64	18
66 - 68	67	42
69 - 71	70	27
72 - 74	73	8
		$\Sigma 100$

Develop an appropriate frequency distribution for the loading times.

Table 4. Exponential Distribution Fitting

Distribution time interval, min	Translated dumping time interval, min	Number of observations	Observed		Theoretical	
			Relative frequency	Cumulative frequency	Relative frequency*	Number of observations
0.545-0.745	0.0-0.2	27	0.62	0.62	0.65	28.60
0.745-0.945	0.2-0.4	11	0.25	0.87	0.23	10.12
0.945-1.145	0.4-0.6	4	0.09	0.96	0.08	3.52
1.145-1.345	0.6-0.8	1	0.02	0.98	0.03	1.32
1.345-1.545	0.8-1.0	1	0.02	1.00	0.01	0.44
		44	1.00		1.00	44

*Example of theoretical relative frequency calculation:

$$\text{Note } f(x) = 5.13e^{-5.13x}, \quad \alpha > 0, x > 0$$

$$F(x) = \int_0^x 5.13e^{-5.13x} dx = 1 - e^{-5.13x}$$

$$P_r (0.0 < x < 0.2) = 1 - e^{-5.13x} \Big|_0^{0.2} = 1 - 0.3584 = 0.6416 \sim 0.65$$

Solution

Plot the histogram of the data (Fig. 5). The histogram of the observed values suggests that the truck loading times may be normally distributed.

The mean and standard deviation of the observed data are:

$$\bar{x} = \frac{\sum f_i x_i}{\sum f_i} = \frac{6745}{100} = 67.45 \text{ sec}$$

$$s^2 = \frac{\sum f_i (x_i - \bar{x})^2}{\sum f_i} = \frac{852.75}{100} = 8.53 \text{ sec}$$

$$s = 2.92 \text{ sec}$$

The observed and theoretical frequencies are calculated in Table 5.

Chi-Square Goodness of Fit

$$\chi^2 (2 \text{ df}) = \sum_{i=1}^n \frac{(o_i - e_i)^2}{e_i} = \frac{(5 - 4)^2}{4} + \frac{(18 - 21)^2}{21} + \frac{(42 - 39)^2}{39} + \frac{(27 - 28)^2}{28} = 0.833$$

$$\chi^2_{0.975} (2 \text{ df}) = 7.38 \quad \chi^2_{0.025} (2 \text{ df}) = 0.51$$

At 95% confidence level, it is concluded that the truck loading times are normally distributed. In a simulation run, the loading time for a truck will be calculated as

$$LT = 67.45 + R_N * 2.92 \text{ sec}$$

where R_N = random normal number with $\mu = 0$, $\sigma^2 = 1.0$.

Example 10

A study on the number of tire failures per week in a surface mine revealed the following data for one year.

Number of tire failures/week x_i	Number of weeks f_i
0	23
1	17
2	7
3	2
4	1
5 or over	0

Examine the probability distribution of the data.

Fig. 5. Histogram for data in example 9.

Solution

Assuming that tire failures occurring during a week are independent, then the number of tire failures per week may be poisson distributed.

$$\bar{x} = \frac{\sum f_i x_i}{\sum f_i} = \frac{41}{50} = 0.82$$

The observed frequencies will be compared with the expected or theoretical frequencies of a poisson distribution with the parameter $\lambda = 0.82$.

Theoretical relative frequency:

$$f(x) = \frac{\lambda^x e^{-\lambda}}{x!} = \frac{(0.82)^x e^{-0.82}}{x!} = \frac{0.44(0.82)^x}{x!}$$

Table 5. Normal Distribution Fitting

Class boundary x_i	Class i	Z for class boundary $Z = \frac{x_i - \mu}{\sigma}$	Area under normal curve from $-\infty$ to Z P_i	Area for each class- A_i $P_{i+1} - P_i$	Expected frequency $N \times A_i$ e_i	Observed frequency f_i o_i
59.5		-2.72	0.0037			
62.5	59.5-62.5	-1.70	0.0446	0.0409	4.09 ~ 4	5

68.5	65.5-68.5	0.36	0.6406	0.3892	38.92 ~ 39	42
71.5	68.5-71.5	1.39	0.9177	0.2771	27.71 ~ 28	27
74.5	71.5-74.5	2.41	0.9930	0.0753	7.53 ~ 8	8

Distribution Fitting: Note that $Z = \frac{x_i - \mu}{\sigma}$. Approximate μ by \bar{x} and σ by S , i.e., $\mu = 67.45$ and $\sigma = 2.92$. $N = 100$ observations.

Table 6. Poisson Distribution Fitting, $\lambda = 0.82$

Number of tire failure/week	Observed		Theoretical	
	Number of weeks	Relative frequency	Relative frequency	Number of weeks
0	23	0.46	0.44	22
1	17	0.34	0.36	18
2	7	0.14	0.15	7.5
3	2	0.04	0.04	2.0
4	1	0.02	0.01	0.5
5 or over	0	0.00	0.00	0.0
	$\Sigma = 50$	$\Sigma = 1.0$	$\Sigma = 1.0$	$\Sigma = 50$

Even without the application of the chi-square goodness of fit test, it is apparent from Table 6 that there is an excellent fit between the observed and expected (or theoretical) data (i.e., number of weeks). It is concluded that the number of tire failures per week can be estimated by a poisson distribution with $\lambda = 0.82$.

It is desirable to fit experimental data or observations to well known probability density functions. The reason for this is that all the knowledge about the known probability density function is readily applicable to understand the process and generate statistical relationships. With some data this may not be possible. In these cases, it is necessary to develop an empirical density function. Empirically, the probability of an outcome is measured by the relative frequency of that outcome. Therefore, an empirical density function associates relative frequencies with outcomes (Maisel and Gnugnoli, 1972). An example of a data set that may not reasonably fit a known density function is the data on delay duration times. The time during which the equipment is not working, as collected during time studies, may be made up of time to service the delays associated with such things as the mechanic availability, the spares required, and the ready availability of the spares. In these cases, the data is the result of many processes interacting with each other (such as age of the equipment, maintenance policy, number of mechanics, delays other than equipment downtime, etc.). Therefore, it may not be possible to fit the data to a well-known density function. Use of an empirical density function in this case is appropriate.

Example 11

The following grouped data represents the load on a 68-t (75-st) truck.

Amount of ore st	Number of truck loads
69-70	2
70-71	4
71-72	2
72-73	4
73-74	8
74-75	12
75-76	10
76-77	4
77-78	10
78-79	8
79-80	8

Fit a density function to this data for use with simulation experiments.

Solution

From an examination of the histogram of the values (Fig. 6), it is concluded that there seems to be no particular known distribution to which the data may be fitted. Therefore, an empirical density function will be developed for the data (Table 7).

If it is assumed that the load on a truck is a *continuous* variable, in the range 63 through 73 t (69 through 80 st), then the empirical distribution will be continuous. If it is assumed that the load on the truck is *discrete*, then the empirical distribution will be discrete. These are shown in Fig. 7. For generating a load on a truck, Monte Carlo sampling will be employed. Depending on the type distribution fitted, whether continuous or discrete, there is a small difference in the values for the load on the truck. In practice, the manner in which a variable is treated, continuous or discrete, is fairly obvious.

A common problem that one encounters in materials handling system is matching the various pieces of equipment in order to minimize unnecessary delays. A typical problem is the number of trucks to be assigned to a loading shovel. If the number of trucks is too low, the shovel wait time may

Fig. 6. Histogram for data in example 11.

Table 7. Empirical Distribution Fitting

Weight of the load, internal	Mid-point	Number of truck loads	Relative frequency	Cumulative frequency
69-70	69.5	2	0.0278	0.0278
70-71	70.5	4	0.0556	0.0833
71-72	71.5	2	0.0278	0.1111
72-73	72.5	4	0.0556	0.1667
73-74	73.5	8	0.1111	0.2778
74-75	74.5	12	0.1667	0.4444
75-76	75.5	10	0.1389	0.5833
76-77	76.5	4	0.0556	0.6389
77-78	77.5	10	0.1389	0.7778
78-79	78.5	8	0.1111	0.8889
79-80	79.5	8	0.1111	1.0000
		$\Sigma = 72$	$\Sigma = 1.0000$	

be prohibitively high. If the number of trucks is too high, then the truck wait time may be too costly. While the general objective is to minimize the shovel wait time, a more appropriate objective may be to minimize the total waiting costs. Defining M and N as the number of shovels and trucks in the system, and C_s as the cost of shovel waiting time (\$/hr), C_t as the cost of truck waiting time (\$/hr), W_m as the cumulative shovel wait time in a shift, and W_n as the cumulative truck wait time in a shift, it is clear that

$$W_m = F_1(M, N)$$

$$W_n = F_2(M, N)$$

$$C_T = W_m * C_s + W_n * C_t$$

where F_1 and F_2 are functional operators and C_T is the total cost of wait times in a shift.

It is clear that, except in very simple systems, W_m and W_n are not easily determined as a function of M and N . The next example illustrates the application of simulation to determine the values for W_m and W_n .

Example 12

Consider an operation where two shovels are engaged in loading six trucks. The shovels are close enough for the trucks to be loaded by the next available shovel.

The truck loading time is normally distributed with mean = 4 min and standard deviation = 1.0 min. The time each truck is away from the shovel (i.e., travel loaded, dump, and travel empty times and any delays on the haul road and the

dump) is also normally distributed with mean = 16 min and standard deviation = 2.0 min.

Set up a simulation experiment to evaluate (1) the shovel wait times for the trucks, and (2) the truck wait times for the shovel. Assume that all six trucks are at the shovels at the start of the simulation.

Solution

Note that all calculated times are rounded off to the nearest first decimal point.

Step 1

LT_i = Time to load a truck by the i th shovel

TA_j = Time away from the shovel for the j th truck

The following equations are established to calculate the various times:

$$\begin{array}{l|l} LT_1 = 4 + RN_1 * 1 & TA_3 = 16 + RN_5 * 2 \\ LT_2 = 4 + RN_2 * 1 & TA_4 = 16 + RN_6 * 2 \\ TA_1 = 16 + RN_3 * 2 & TA_5 = 16 + RN_7 * 2 \\ TA_2 = 16 + RN_4 * 2 & TA_6 = 16 + RN_8 * 2 \end{array}$$

where

RN_k is the k th random normal number stream. Note that the first eight columns in Table 3 has been chosen for the eight random number streams.

Step 2

Calculation of loading times for shovel 1 ($LT_1 = 4.0 + RN_1 * 1.0$) and shovel 2 ($LT_2 = 4.0 + RN_2 * 1.0$)

Fig. 7. Cumulative distribution function for data in example 11.

Shovel 1		Shovel 2	
RN_1	LT_1	RN_2	LT_2
0.464	4.5	0.137	4.1
0.060	4.1	-2.526	1.5
1.486	5.5	-0.354	3.6
1.022	5.0	-0.472	3.5
1.394	5.4	-0.555	3.4
0.906	5.0	-0.513	3.5
1.179	5.2	-1.055	3.0

-0.531	14.9	-0.194	15.6	0.543	17.1	-1.558	12.9	0.187	16.4	-1.190	13.6
-0.634	14.7	0.697	17.4	0.926	17.9	1.375	18.8	0.785	17.6	-0.963	14.1
1.279	18.6	3.521	23.0	0.571	17.1	-1.851	12.3	0.194	16.4	1.192	18.4
0.046	16.1	0.321	16.6	2.945	21.9	1.974	19.9	-0.258	15.5	0.412	16.8
-0.525	14.9	0.595	17.2	0.881	17.8	-0.934	14.1	1.579	19.2	0.161	16.3
0.007	16.0	0.769	17.5	0.971	17.9	0.712	17.4	1.090	18.2	-0.631	14.7
-0.162	15.7	-0.136	15.7	1.033	18.1	0.203	16.4	0.448	16.9	0.748	17.5
-1.618	13.8	-0.345	15.3	-0.511	15.0	-2.051	11.9	-0.457	15.1	-0.218	15.6
0.378	16.8	0.761	17.5	0.181	16.4	-0.736	14.5	0.960	17.9	-1.530	13.9

Step 4

Set up two registers, one for recording the status of the shovels and another for recording the status of the trucks (Tables 8 and 9).

Define: M = Number of shovels in the system
 N = Number of trucks in the system
 $ESTS_i$ = Elapsed shift time of shovel i , $i = 1, 2, \dots, M$
 $ESTT_j$ = Elapsed shift time of truck j , $j = 1, 2, \dots, N$
 ST = Time span for simulation (e.g., one shift, one month, etc.)

The procedure to simulate follows:

Step 4(a). Choose the truck with the smallest elapsed shift time (EST).

Let it be the k th truck with $EST = ESTT_k$.

If ($ESTT_k > ST$), go to Step 4(h).

Step 4(b). Choose the shovel with the smallest elapsed shift time (EST).

Let it be the g th shovel with $EST = ESTS_g$.

Step 4(c). Let $(ESTS_g - ESTT_k) = w$

(1) if $w < 0$, go to Step 4(d)

(2) if $w > 0$, go to Step 4(e)

(3) if $w = 0$, the truck can be assigned to the shovel immediately. Go to step 4(f).

Step 4(d). Shovel g is waiting for a truck. The waiting time of the shovel, w_s

$$w_s = ESTT_k - ESTS_g$$

Update the EST status of shovel g

$$ESTS_g = ESTS_g + w_s$$

Go to Step 4(f).

Step 4(e). Truck k is waiting for the shovel to be available.

The waiting time of the truck, w_t , is

$$w_t = ESTS_g - ESTT_k$$

Update the EST status of truck k

$$ESTT_k = ESTT_k + w_t$$

Step 4(f) Generate a load time for the k th truck by the g th shovel.

Let this time be L_{gk}

Update the EST status of the shovel and the truck

$$ESTS_g = ESTS_g + L_{gk}$$

$$ESTT_k = ESTT_k + L_{gk}$$

Step 4(g). Generate a time away from the k th truck from the loading shovels. Let this time be, t_k

Update the EST status of the k th truck.

$$ESTT_k = ESTT_k + t_k$$

Go to Step 4(a).

Step 4(h) Simulation time has been exceeded. Summarize the results.

- (1) Total production, truck loads or tons
- (2) Number of trips/truck

Activity Code: L_k = Loaded by k^{th} shovel;
 TA = time away from shovel;
 W = waiting for shovel.
 EST = Elapsed shift time.

(3) Waiting time of each truck to shovel

(4) Waiting time shovel for trucks.

As an example of the procedure, consider the status of the various equipment in the system at about 15 min into the shift. From the shovel status table, it is seen that shovel 1 has loaded three trucks, specifically trucks 1, 4, and 6 from the time simulation began. Its elapsed shift time (EST) is 14.1 min. Also, shovel 2 has loaded three trucks, specifically trucks 2, 3, and 5 and its EST is 9.2 min.

Checking on the truck status table, it is seen that all the trucks are away from the shovel and that truck 1 will be back at shovels at an EST of 25.4 min, truck 2 at an EST of 19.5 min, truck 3 at 21.5 min, truck 4 at 25.2 min, truck 5 at 24.6 min, and truck 6 at 32.7 min.

Using the notation above,

Step 4(a): $k = 2$ $ESTT_2 = 19.5$

Step 4(b): $g = 2$ $ESTS_2 = 9.2$

and

Step 4(c): $ESTS_2 - ESTT_2 = 9.2 - 19.5 = -10.3$

Therefore, shovel 2 is waiting for trucks and this waiting time is 10.3 min.

Step 4(d): $ESTS_2 = 9.2 + 10.3 = 19.5$

At Step 4(f), truck 2 is loaded by shovel 2, and the loading time is 3.5 min (see Step 2, shovel 2).

Step 4(f): $ESTS_2 = 19.5 + 3.5 = 23.0$

$ESTT_2 = 19.5 + 3.5 = 23.0$

At Step 4(g) for truck 2, the time away from shovels (TA) is generated. This is 15.6 min (see Step 3, truck 2).

Step 4(g): $ESTT_2 = 23.0 + 15.6 = 38.6$
 i.e., truck 2 will be back at the shovels at an EST of 38.6 min. The procedure is returned to Step 4(a), and it is seen that now $k = 3$, $ESTT_3 = 19.5$, and Step 4(b), $g = 1$, $ESTS_1 = 14.1$. The status of shovel 1 and truck 3 will be updated using the above procedures and simulation will continue up to the time specified for the experiment. In this example, the simulation time was specified as at least 100 min of truck operation.

The results of this 100 min of simulation are:

Number of truck loads from shovel 1 = 14

Number of truck loads from shovel 2 = 16

Total production = 30 truck loads

Number of trips: Truck 1 = 5

Truck 2 = 5

Truck 3 = 5

Truck 4 = 5

Truck 5 = 5

Truck 6 = 5

Total truck loads = 30

Shovel waiting times:

shovel 1 for trucks = 39.1 min

shovel 2 for trucks = 36.6 min

Total shovel wait time = 75.7 min

Truck wait times: truck 1 = 5.8 min

truck 2 = 0 min

truck 3 = 4.1 min

truck 4 = 14.2 min

truck 5 = 9.1 min

truck 6 = 13.2 min

Total truck wait time = 46.4 min

It is readily seen that by adding more trucks to the system, the shovel waiting time can be decreased. Note that, on the average, there can be five trucks assigned to each shovel:

Average truck cycle time = $16 + 4 = 20$ min
 (average TA + average LT)

Average load time = 4 min

Number of trucks/shovel = $20/4 = 5$

The above simulation exercise can now be continued with seven, eight, nine and ten trucks. The objective is to minimize the total cost of shovel waiting time and truck waiting time.

Obviously, it is very time-consuming and tedious to simulate this simple problem for over 100 min. However, the procedure can be easily programmed for the computer.

A generalized flow diagram of how such a computer program can be used to select the number of trucks assigned to a shovel is shown in Fig. 8.

TRUCK/RAIL MOVEMENT SIMULATION

The mathematical modeling of the movement of a haul unit can be attempted by both deterministic and probabilistic approaches. From basic mechanics, the continuous change of the position of a body can be established. Consider the following definitions.

f = force, (kg) lb

m = mass kg-s²/m (lb-sec²/ft)

a = acceleration, m/s² (ft/sec²)

V_t = velocity at time t , m/s (ft/sec)

S = distance traveled in the time interval $(0, t)$, m (ft)

V_o = velocity at time 0, m/s (ft/sec).

By definition, $a = f/m$; acceleration will be constant only when for a constant mass, the force exerted does not change. Under constant acceleration conditions,

$$d_v = a * d_t \text{ and } d_t^2 = a * d_t^2$$

and, it will be a simple step to integrate these equations to find the velocity and distance traveled as a function of time. In fact, at time t ,

$$V_t = V_o + a * t, \text{ and } S = V_o * t + (1/2) a * t^2$$

In mine haulage, however, the assumption of constant acceleration does not generally hold for all the trips. The force needed to create the acceleration is a function of the speed-rimpull characteristics of the equipment, the coefficient of adhesion between the vehicle wheels and the road surface, the load on the truck, and the frictional and gradient resistance of the haulage profile. The load on the truck may not be constant every trip. Consequently, the frictional and gradient resistances, the accelerating force and acceleration, all vary over the same haul road profile. In addition, as the number of trucks in the system increases, there may be mov-

ing queues. Two approaches have been used to capture this variation in truck/rail travel times, namely deterministic simulation and probabilistic simulation.

Deterministic Simulation

In the deterministic approach vehicle motion is simulated for increments of a small interval of time, Δt . During this small time interval, acceleration is assumed to be constant, and using the force-mass-acceleration relationship, and the motion formulas, the velocity and position of the vehicle are determined at the end of the time interval. The required data for this simulation include the speed-rimpull characteristic of the equipment, specifications of the haul road profiles such as length, gradient, and maximum speeds, and maximum accelerations. The simulation approach can be explained with reference to Figure 9, the speed-rimpull characteristics of a truck and the haul road profile, respectively. The total weight of the truck will be:

$$W_T = W_o + W_c$$

W_T = total weight of the trucks, st

W_o = tare weight of the truck, st

W_c = weight of ore (or waste) loaded, st.

The rolling resistance in lb/st and grade of the section X-Y in percent are K and G , respectively, and the acceleration due to gravity is g ft/sec². Assuming that this truck is at Junction X at time t with velocity V_1 mph, and that the acceleration of the truck is constant for the time increment Δt , the following can be developed:

Available rimpull at X = R_1 lb

Resistance to motion = $(G + K) * 20 * W_T$ lb

Acceleration force = $(R_1 - (G + K) * 20 * W_T)$ lb

a = acceleration

$$= \frac{(R_1 - (G + K) * 20 * W_T)}{(W_T + 2000)/g} = \text{ft/sec}$$

Defining V_2 as the velocity at time $t + \Delta t$, and D as the distance traveled in time Δt , it is seen that

$$V_2 = V_1 + a * \Delta t$$

$$D = V_1 * \Delta t + (1/2)a * (\Delta t)^2$$

Now, the available rimpull at the location X_1 in the haul road section, as can be seen from the rimpull curve, is R_2 . This will determine a new acceleration force and therefore, new acceleration, for the next time interval Δt , which in turn will be used to calculate the distance traveled and the velocity in that interval. These steps are repeated until the entire Section X-Y is traversed. At the end of Section X-Y, data is initialized for the next haul road segment and the simulation is continued until the haul unit reaches the dump.

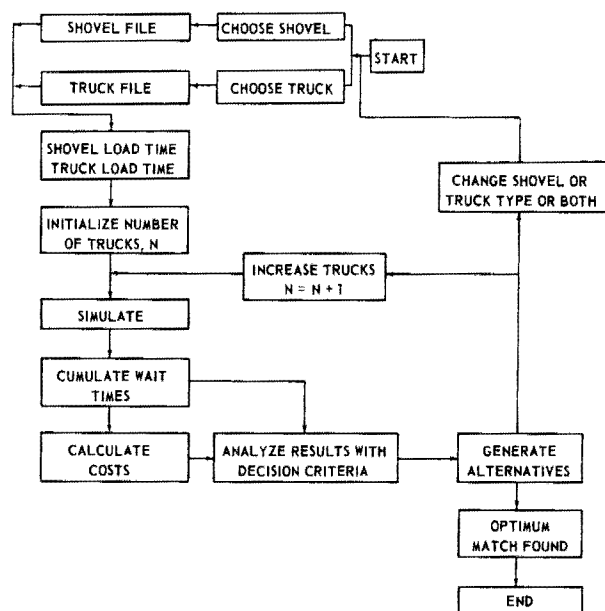

Fig. 8. Generalized flow diagram for truck selection.

Fig. 9. Simulation of motion in a computer model.

There can be some significant differences in the results obtained from the two approaches. In the deterministic approach, the truck-travel times are generated as a function of the load on the truck. In probabilistic simulation, unless the travel time distributions are conditioned by the truck load, the generated travel times will be independent of the truck load; this is not true. On the other hand, the deterministic approach may give optimistic results for travel times as it does not include operator variability. Operator variability is automatically incorporated in the time-study generated travel-time distributions. When a new mine is being planned or major changes are planned in existing mines, time study data for these conditions is nonexistent. Historical time-study data has to be adjusted on the basis of experience to develop input for the changed conditions. Such limitations do not exist in the deterministic approach. Finally, the predicted performance of the deterministic method may serve as the standard for comparing operator performance. In practice, for shovel-truck systems, considerable data is to be collected for both the approaches. Depending on the purpose of the study, either approach or both can be advantageously used.

Monte Carlo based shovel-truck models can be explained by reference to Fig. 11, where ore is moved from various shovel locations, along a network of haulage routes, to several dumping stations (Bauer and Calder, 1973). Through extensive time studies in the field, data is collected on the load times, the travel times, and dump times. Depending on the detail of the model, the haul road may be broken down into a number of distinct segments. The time to travel each segment is collected. The magnitude of the data collection effort depends on such factors as the number of different types of shovels and trucks employed, of the number of haul road segments in the haul route, the number of dump locations, and the operating procedures. Empirical or standard statistical distributions can be fitted to the observed load, travel, and dump times. These distributions permit the *random* se-

Essentially, a shovel-truck model, using a computer, cycles trucks between their assigned shovels and dumps over specified haul routes. Records are kept of all waiting times at the loading and dumping points, and at haul road intersections, and of the ore and waste production. A shovel truck simulation model can have a number of applications including equipment selection, equipment performance analysis, equipment assignment, equipment scheduling, production planning, mine layout planning, and haul road design.

BELT SIMULATION

Proper design of a conveyor belt system to handle the desired material flow rate involves many things, material characteristics such as density, lump size, percent fines; conveyor data such as width, length, angle of incline, lift (or drop), and speed; drive related information such as location and number of drives, type of motor, and horsepower; belt support data such as idlers, their spacings and angles; and loading conditions such as number of loading points and loading rates. In the design of a haulage system consisting of only one belt and one loading point, it may not be too difficult to establish an optimum flow rate for the belt. Even here one has to consider the adequacy of the surge capacity at the loading point for unexpected belt breakdowns. In typical mine application, however, a face belt may be loaded from several sources. In addition this belt may feed a submain or gathering belt, which in turn may feed a primary or mother belt (Fig. 12). In this belt network the problem of belt selection is compounded by many additional factors, such as (1) the arrival time of the loads on each belt, (2) the length of the loads on each belt, (3) the relationships between the various belt loading points and discharge points, and (4) the location and amount of surge capacity in the system. Unless the entire system is laid out with detailed consideration to each of these factors, peak loads of unknown magnitude and frequency can result. The need for the use of computer simulation techniques to design a belt network is obvious.

Fig. 12. Surface mine belt network.

The first realistic simulation model of mine belt networks, based on probabilistic simulation of arrival of loads on a belt was developed in 1965 by Sanford and Manula. Bucklen, et al. (1968), developed an improved belt haulage simulator based on the first model. In 1969, Sanford and Manula developed a time-increment belt simulator to integrate the belt network with other components of the production system to develop a more complete materials handling simulator. Tan Sizhe (1985) has developed a fairly complex belt simulation model which incorporates variable feeder and discharge locations and several modes for describing the load arrivals to the belt.

MATERIALS HANDLING SIMULATOR

The real potential of the simulation technique is not fully realized when it is used to develop a model of a single entity such as a truck, a rail, or a belt in a mine. Since all the haulage units in a system interact with each other, there is a need to consider all the units at one and the same time. The simplest relationship may be with the loading shovels and a crusher system. A more complex relationship may be similar to the one portrayed in Fig. 13, a sequence of materials handling activities from two mines. A fairly detailed Open Pit Materials Handling Simulator (OPMHS) is available for the planning and analysis of excavation and transportation activities in surface mining operations (Ramani and Manula, 1978). This simulator consists of a number of sub-assemblies which can be used in any order to model a surface mine (Fig. 14). The load subassembly incorporates bucket-wheel excavators, stripping dragline, stripping shovel, and

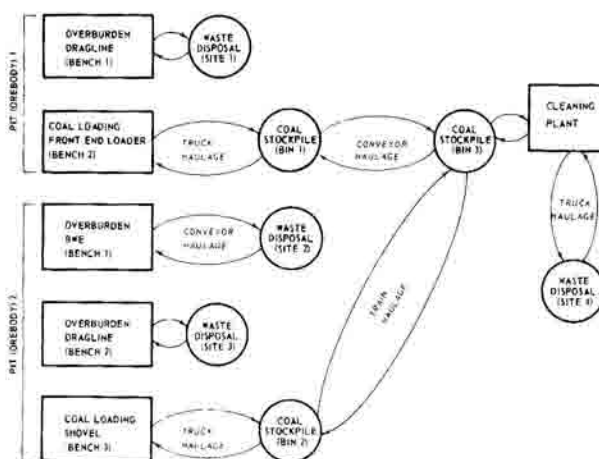

Fig. 13. Complex materials handling scheme in a surface coal mine in competing draglines, loaders, trucks, belts, and trains.

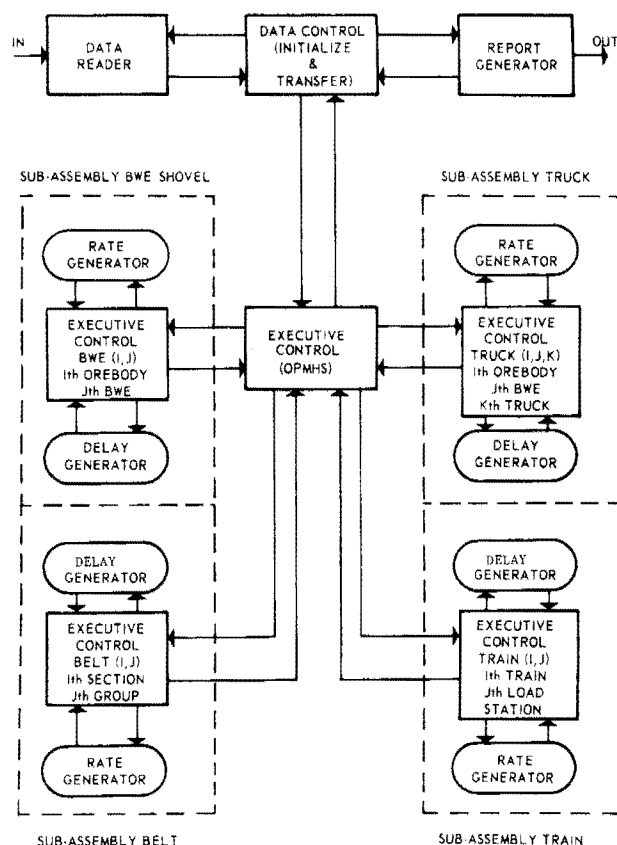

Fig. 14. Flow diagram of the open pit materials handling simulator.

loading shovel. The haulage assembly incorporates trucks, belts, and trains. There are provisions for surge bins and stockpiles. Using a combination of deterministic and probabilistic, and time-increment and event-oriented simulation, the equipment and materials are moved through the mining system. The output includes production and equipment performance and delay statistics. The simulator has been applied to a number of operations of varying complexities. A new version of this simulator incorporating geological and equipment characteristics for describing production has been recently released (Ramani and Albert, 1985).

SIMULATION LANGUAGES

Computerization of the mathematical model is an important step in a simulation study. The simulation model is, in fact, a computer program. The choice of the language for writing the computer program is a major decision. There are multipurpose languages, such as FORTRAN, ALGOL, and APL and simulation specific languages, such as GPSS, GASP, SIMSCRIPT, CSMP, DYNAMO, and SLAM. The applicability of the language will be determined by the scope and orientation of the simulation model. Where the model is extremely procedure-oriented, involving a number of complex decision-processes and logical relationships, such as the deterministic simulation of motion, the use of a multipurpose language will be the safest choice. On the other hand, where the model is generally process-oriented involving the flow of discrete items at discrete points in time, such as the Monte Carlo simulation model, a simulation language would be

natural to use. Simulation of inventory and waiting line processes can be ideally carried out in a simulation language. These broad generalizations are provided here only to indicate the importance of this subject rather than to serve as guidelines. Mine materials handling simulators have been developed in some of the simulation languages. However, the use of a multipurpose language, particularly FORTRAN, has been the general trend.

SUMMARY

There is little doubt that experience and judgement are important for decision-making in systems characterized by complex interactions of technical, economic, and social components, and by a large number of risky outcomes. However, quantitative analysis of many aspects of the system, as an aid to decision-making, is feasible. One such system is the materials handling system in surface mines. Simulation models of materials-handling systems such as shovel-truck and belt conveyor networks are available. These models provide an insight into the complex interactions that take place in real world systems, and enable the decision-maker to select alternatives for the system under evaluation to enhance desirable interactions and suppress undesirable consequences. Thus, simulation models are useful for planning new mines and evaluating operating mines. However, in the real world, fluctuations in performance will be encountered due to changes in weather, road conditions, age and wear and tear of the equipment. These conditions may go unsimulated. It is often necessary to adjust the simulation results with factors to approximate the expected average performance. Finally, simulation is an experimental technique. A simulation model's purpose is to help the decision-maker select the best values of the controllable variables to obtain the best system performance. Even with a good simulation model, efficient experimental design is required to decipher, at acceptable cost, the relationships between the controllable variables, the uncontrollable variables, and the measures of performance.

6.5.9 Haulage System Analysis: Queuing Theory

JORGEN ELBROND

INTRODUCTION

In an open pit operation the trucks move from the shovels to the dump-crusher and back. Sometimes they go to the repair shop or to the fueling station; they regularly go to the places where drivers are exchanged and where meals are taken. Occasionally the trucks have to wait at a shovel, at the dump-crusher, at the repair shop or at the fueling station when there already is a truck being loaded at the shovel or being fueled or when all positions at the dump-crusher or all bays at the repair shop are occupied. These situations are caused by variabilities of the loading, dumping, repair, and fueling times and of the time intervals between trucks arriving at these facilities.

These waiting times reduce the capacity of the operation. It is quite obvious that the waiting times increase when trucks are added to an existing system if no other changes are made to the system. The productivity per truck will thus decrease (while the productivity of the shovels will increase).

The estimation of these waiting times is an important task in the design and equipment selection for a new open pit operation or when changes in an existing operation are being considered. Also important is the estimation of the trucks' travel times, full and empty, on the pit roads, for example by a truck performance calculator, and the estimation of the loading, dumping and repair times.

The estimation of waiting times is the subject of operations research techniques such as simulation by random numbers or the queuing theory. These techniques together with the performance calculators of trucks and shovels are important tools in the design process, in equipment selection, and in the management of the daily operation.

The queuing theory offers an interesting approach to the estimation of waiting times because of its calculation speed and its relative simplicity compared with simulation by random numbers. Sometimes the queuing approach can completely substitute simulation; sometimes it offers an interesting supplement to simulation in that it can fill in missing points in a simulation study quickly and cheaply. In truck dispatching, where a forward estimate of waiting times is important information for the dispatcher, it offers the only way fast enough to provide that information.

WAITING TIME IN A CLOSED CIRCUIT

The waiting time of clients returning to a server in a closed circuit (Fig. 1) is a function of the service time (TS),

Fig. 1. Closed circuit with one server.

its standard deviation (SRT), the return time of clients (RT), its standard deviation (SRT), and the number of clients (N) in the circuit. Mathematical solutions of the waiting time are found in the following cases:

1. Service time, TS , of random length, $STS=TS$, and return time, RT , of random length, $SRT=RT$. In this solution, from Palm (1947), the waiting time is called WP . Posner and Bernholtz (1967) have shown that this solution is valid regardless of the standard deviation, SRT , of the return time, RT ; a result which is used in the interpolation procedure described later.

2. Service time, TS , of constant length, $STS=0$, and return time, RT , of random length, $SRT=RT$. This solution, called WA , is from Ashcroft (1957).

3. Both service time, TS , and return time, RT , constant. $STS=0$, $SRT=0$. This is the trivial case. This waiting time is called WB .

The formulas are shown in Appendix I.

ADJUSTMENT TO INDUSTRIAL SITUATIONS

In an industrial circuit one would find neither random nor constant return times, but often would find service times which are less random but not constant. In repair shops service times tend to be random. Using the previous mathematical solutions supported by a series of simulation experiments, an interpolation procedure (Fig. 2) has been developed. The axis are the coefficients of variation of the service time, STS/TS , and of the return time, SRT/TR . The adjusted waiting time, WS , is a linear combination of WP , WA , and WB . The waiting time of trucks in shovel/dump circuits is mostly situated at STS/TS and SRT/RT both being about 0.3 (Elbrond, 1974).

Fig. 2. Interpolation procedure.

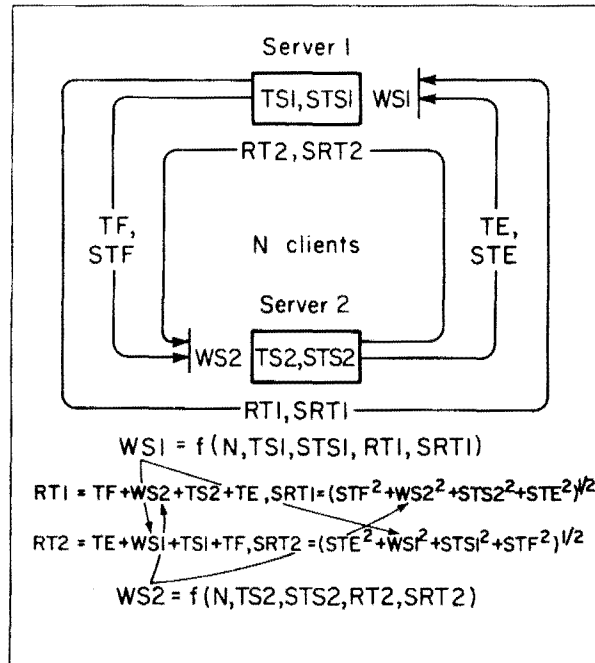

Fig. 3. Circuit with two servers in series.

THE CIRCUIT WITH TWO SERVERS IN SERIES

The circuits in which the trucks in an open pit operation are moving have at least two servers, a shovel and a dump-crusher. As there is no mathematical solution to the waiting times at the two servers when neither service times nor return times are of random length, a special procedure (Fig. 3) has been developed, whereby the waiting time ($WS1$) at the first server is calculated using the service time ($TS1$) and the return time ($RT1$), which is known and which is the sum of the travel time (TF) to the second server, its service time ($TS2$) and the travel time (TE) back to the first server. The standard deviation ($STS1$) of the service time is known and the standard deviation ($SRT1$) of the return time is estimated as the statistical sum of the components' standard deviations (Elbrond, 1974; 1977).

The calculation is then reversed to the second server, whereby the waiting time ($WS2$) at this server is calculated using the service time ($TS2$) and the return time ($RT2$), which is now known, namely the sum of the travel time to the first server (TE), the just calculated waiting time at the

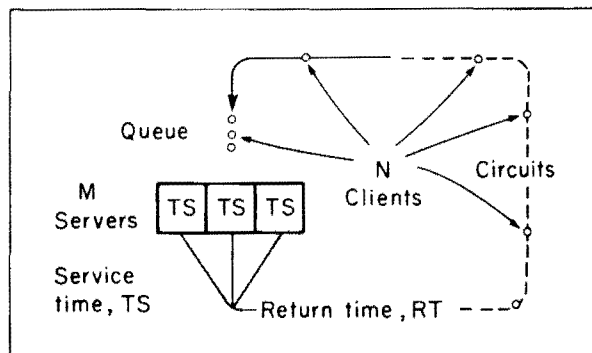

Fig. 4. Circuit with parallel servers.

first server ($WS1$), its service time ($TS1$), and the travel time back (TF). The standard deviation of the service time ($STS2$) is known and the standard deviation of the return time ($SRT2$) is estimated as the statistical sum of the components' standard deviations, whereby the standard deviation of the estimated waiting time is assumed to be equal to the waiting time itself. The procedure then reverses to the first server to calculate a new waiting time using the newly calculated waiting time at the second server in the return time. The procedure converges rapidly. There is no mathematical proof for this procedure. It has, however, been possible to verify waiting time estimates by time studies. The convergence bears some resemblance to a real operation where waiting times also may oscillate.

CIRCUITS WITH PARALLEL SERVERS

A service station may consist of two or more servers working in parallel (Fig. 4). This would be the case of a dump-crusher with two dumping positions, provided that the crusher is capable of absorbing two truckloads at a time, and also the case of a repair shop for trucks with several repair bays. If the servers have equal random service times and are fully collaborating with a common queue, then the waiting time can be calculated by means of a procedure (Palm, 1947) which is similar to the one mentioned earlier but slightly more complex due to the number M of servers.

The formula for the calculation of the waiting time is given in Appendix II. This is the case of repair shops. If the service times of the M fully collaborating servers are not

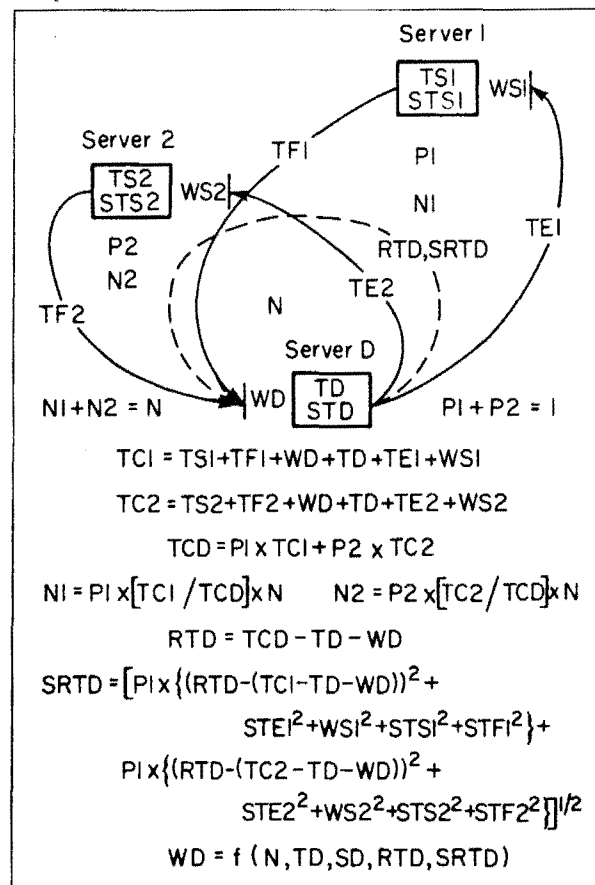

Fig. 5. System with two circuits.

random even though of equal length, the necessary formula does not exist to establish an interpolation formula as the one shown in Fig. 2. In this case it is proposed to calculate the waiting time (WS) as was done in the case of one server and with a number of clients equal to N/M . This WS divided by WP , the waiting time for one server, becomes the correction factor to apply to the waiting time for M servers (Palm, 1947).

The procedure is described in Appendix III. This is the case of a double dump-crusher. In the total procedure described in this section, it is assumed that dispatching of trucks occurs at their departure from the dump-crusher. In this case the shovels are noncollaborating and have individual queues. If the dispatching is effectuated later, a group of shovels could become partly or wholly collaborating with a common queue. The estimation of the resulting waiting time can be made using an approach that finds a weighted average of the noncollaborating case and the totally collaborating case, taking into account the possible different loading times, production rates, and cycle times.

SEVERAL CIRCUITS

In an open pit operation several circuits join at the same dump-crusher. The single circuit concept has been expanded by using a weighted average return time to the common server.

The Two-Circuit System

In a two-circuit system (Fig. 5), the N trucks are first distributed between the two circuits (N_1 and N_2) according to the desired split (P_1 and P_2) of production between the two shovels and to the cycle times (TC_1 and TC_2) in the two circuits. These cycle times are not yet completely known since they must include the waiting times at the shovels (WS_1 and WS_2) as well as at the common dump-crusher (WD). The initial truck distribution is therefore made only according to the split and the net cycle times (without waiting times). The waiting time at the shovel in the first circuit is then calculated using the procedure developed in the preceding paragraphs, followed by the calculation of the waiting

time at the shovel in the second circuit. Then the weighted return time (RTD) to the common dump-crusher is calculated from the weighted cycle time (TCD) minus the dumping time (TD) and minus the waiting time (WD) at the dump. The standard deviation ($SRTD$) of the return time to the dump-crusher is calculated knowing the production split between the two circuits (P_1 and P_2) and the individual return times' standard deviations. The waiting time (WD) at the dump-crusher can now be calculated using the weighted return time and its standard deviation.

The next step in the calculation is to make an adjustment to the distribution of trucks in the two circuits using the new cycle times, which now include the first estimates of the waiting times at the shovels and the dump-crusher. The procedure is then repeated until convergence, after a few iterations.

Noninteger Number of Trucks: At the truck distribution it will occur that noninteger numbers of trucks are to be distributed. Although the formulas for waiting time can cope with noninteger numbers of clients, except when smaller than 1, it is more appropriate to arrange the calculation so that the waiting time is calculated as the weighted average of the integer above and the integer below the noninteger number of clients. The weights are found from the two integer numbers' deviations from the noninteger. This is also more in line with reality.

Waiting in Line After Interruptions of Operations: Additional waiting time of trucks, prolonging their cycle times, occurs after an interruption of production at the shovel. For example after shift change or after a meal break, all the trucks in a shovel circuit depart from the same place at the same time to arrive in a group at the shovel. Another example is a short breakdown of the shovel, which does not result in rescheduling of the trucks. They will accumulate at the shovel. When the interruption is finished (Fig. 6), the first truck gets loaded immediately whereas the second waits during one loading time, the third waits during two loading times, etc. After some time, which can be estimated to be between $\frac{1}{2}$ and 1 cycle time, the initial waiting time can be assumed to have dropped to the stationary waiting time, which is calculated by the queuing procedure Fig. 7 shows an example of interruptions during an 8-hr shift causing accumulation of trucks at the shovel.

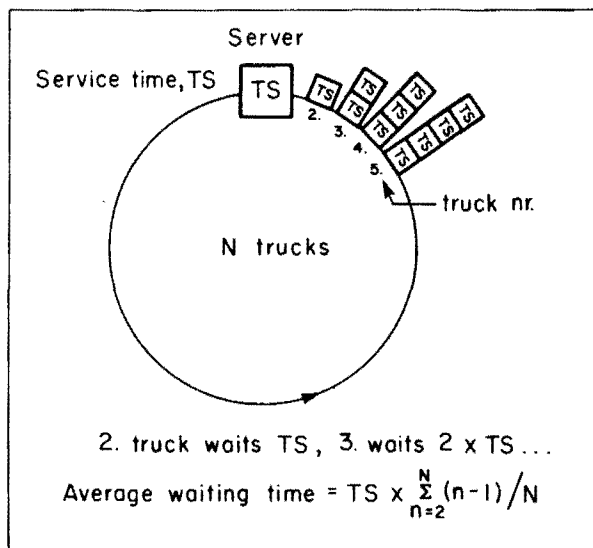

Fig. 6. Accumulation of trucks and initial waiting time.

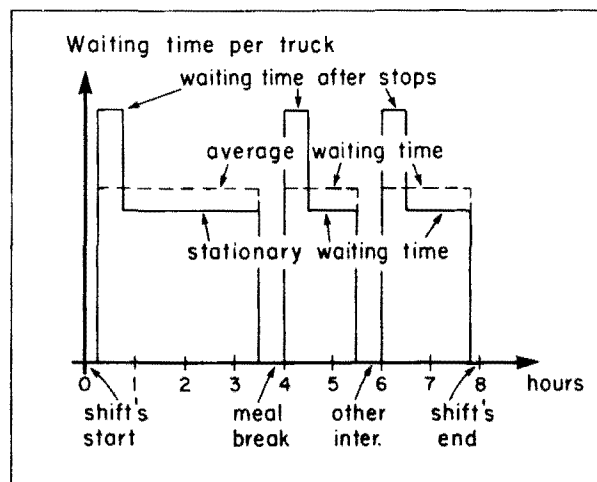

Fig. 7. Shift's composition with initial and stationary waiting times.

Several Circuits with a Common Dump

The expansion of the procedure for two circuits with a common dump-crusher to a procedure with several circuits is easy to conceive (Fig. 8). The return time (*RTD*) from the dump-crusher is now weighted from several circuits as is its standard deviation (*SRTD*).

Several Circuits in Waste and Ore

The procedure can also easily be expanded to include circuits between waste shovels and dumps (Fig. 9). The trucks are distributed according to the split between shovels' production, which now includes the waste/ore ratio, and the cycle times. The only difference between the ore circuits and the waste circuits is that the latter do not normally have waiting time at the dump.

AVAILABILITY

In the discussion so far 100% presence of shovels and trucks has been assumed. All machines are operated according to the desired distribution of production and waste/ore ratio except for the short breakdowns of shovels, which do not lead to the rescheduling of trucks and are not included in the nonavailability figure of the shovels. Their effect on the shovels is included in the available shift production time. The procedure must now be completed with due consideration of the effect of nonavailabilities of shovels and trucks.

The conventional definition of mechanical availability of trucks is the ratio between working hours and the sum of working hours and repair hours. Working hours include the waiting times at shovels and at the dump-crusher and the repair hours include the waiting time outside the repair shop. Since these waiting times are dependent on the system which is being studied, it seems appropriate to introduce a more basic availability measure, from which the conventional mechanical availability and the effective utilization can be worked out. Such a measure could be called the *internal availability* defined as the ratio between functioning hours and the sum of those hours and the effective repair hours. None of the hours should include waiting time at shovels, dump-crusher, or outside the repair shop. This measure could be obtained by monitoring devices installed on the trucks and would reflect the wear and tear of the truck due to its operation. From this internal availability, the effect of the repair shop with its repair bays can be included in the capacity estimation procedure by means of a superimposed repair circuit. The approach is described Elbrond (1979).

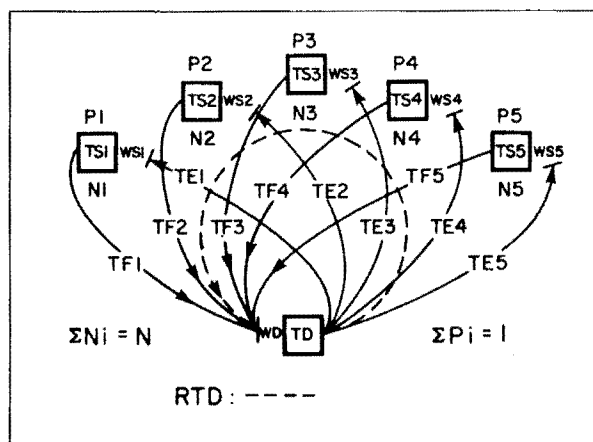

Fig. 8. System with several circuits.

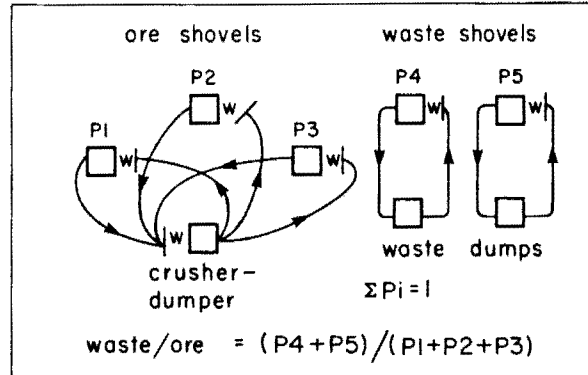

Fig. 9. System with waste and ore circuits.

TRUCKS' REPAIR CYCLES

When trucks break down and need repair, they are taken to the repair shop where they might have to wait if all the repair bays are occupied. An extension of the cycle approach opens the possibility of including the trucks' nonavailability due to breakdowns and of calculating their waiting time ahead of the repair shop by superimposing a repair circuit on the production circuits. In this circuit, the trucks visit the repair facility, consisting of one or more repair bays, according to the internal availability, which is transformed into a number of production cycles between repair cycles by means of the average length of repair (Fig. 10). The simplest approach is made possible by the fact that the lengths of repair tend to be random. For each shovel circuit the number of truck cycles (*Ri*) between repairs is calculated from the internal availability (*η*), the net cycle time (*NTCi*) and the

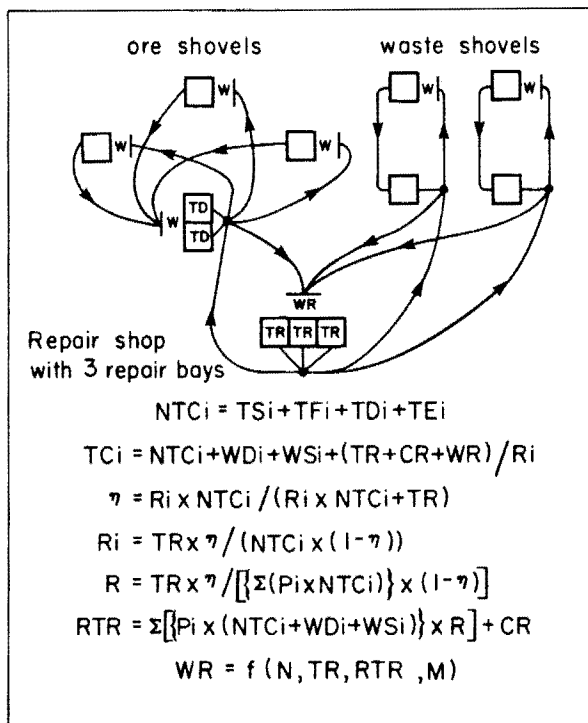

Fig. 10. Superimposed repair circuit.

average length of repair (TR). The total cycle in a shovel circuit (TCi) now includes a fraction of the repair time (TR), of the waiting time (WR) ahead of the repair facility yet to be calculated, and the time it takes to bring the truck to and from the mine (CR). The average number of truck cycles between repairs (R) and the return time to the repair shop (RTR) are found by weighting procedures. The waiting time at the repair shop (WR) is calculated by means of the simple formula for Palm's waiting time in the case of more than one server (Appendix II) from the total number of trucks (N), the repair time (TR), the return time (RTR), and the number of repair bays (M). The calculated waiting times in the shovel circuits and in the repair circuit gradually enter the total cycles, but the procedure converges rapidly.

SHOVELS' AVAILABILITY

When shovels break down, the repair is executed by a repair team at the shovel site. It has been found by observations that the frequencies of shovels' operational presence over a shift can be estimated reasonably well by means of the binomial law (Fig. 11), which expresses the probability $Pn(N)$, of having n shovels present out of N , when the internal availability (η) is known. It is also possible to express the probability of having a given set of shovels present. The shovels do not need to have an identical internal availability, which makes it possible to evaluate the effect of shovels of various internal availabilities.

For a given set of shovels, the trucks are distributed according to a modified split of production between the remaining shovels. The new distribution maintains the pro-

portions between the remaining shovels. This maintains the overall distribution considering all shovel presence combinations.

THE CAPACITY CALCULATION

The total capacity calculation can now be carried out using the models described in the previous paragraphs.

For each set of available shovels, the trucks are distributed according to the modified split of production between shovels. The cycle times in the various circuits are estimated by the adjusted iterative procedures and the capacity per shift of waste and ore, considering the available shift hours, is calculated. The total capacity is obtained by the integration of the probabilities of the various shovel sets' presence with their respective shift's capacity. Information on mechanical availability according to the conventional definition can be obtained as well as the effective utilization. The variation of shift capacity of waste and ore can be estimated.

CALCULATION EXAMPLE AND RESULTS

Five shovels, three in ore and two in waste, $W/O = \frac{2}{3}$ with an internal availability of 0.8, load 20 trucks with an internal availability of 0.8.

Shovel	Loading min.	Travel min.	Dumping min.	Pi
1	5	15	2	0.25 ore
2	5	20	2	0.20 ore
3	5	15	2	0.15 ore
4	4	10	2	0.20 waste
5	4	10	2	0.20 waste

Four repair bays in the repair shop. Average repair time = 720 min. Average time to bring a truck to and from the pit = 120 min. Shift time = 360 min out of 480 min.

Results:

126 truckloads of ore per shift

86 truckloads of waste per shift

Effective utilization of trucks = 0.58.

cessive capacity reductions when including (1) the strict queue waiting time estimates, (2) adding the shift composition and initial waiting times after interruptions, and (3) the availabilities of shovels and trucks.

CONCLUSIONS

The calculation method described in this section provides a means of estimating the capacity of the loading and transportation of material in open pit mines utilizing trucks. It has been verified in practice (Elbrond, Piché, and Caines, 1979) and is easily adjustable. The computer programming is straightforward and computing time is short.

Notations

- TS : Service time
 STS : Standard deviation of service time
 RT : Return time
 SRT : Standard deviation of return time
 N : Number of clients
 $k = TS/RT$
 ρP : Utilization factor of Palm
 ρA : Utilization factor of Ashcroft
 WP : Palm's waiting time
 WA : Ashcroft's waiting time

WB : Waiting time in constant case

WS : Adjusted waiting time

TS, STS, RT, SRT, N

$$k = TS/RT$$

$$\rho P = 1 - \left[1 + \sum_{n=1}^N \prod_{i=1}^n \{(N-i+1) \times k\} \right]^{-1}$$

$$\rho A = \left[1 + \left\{ N \times k \times \left(1 + \sum_{n=1}^{N-1} \prod_{i=1}^n (N-i) \times (e^{k \times i} - 1)/i \right) \right\}^{-1} \right]^{-1}$$

$$WP = N \times TS / \rho P - (TS + RT)$$

$$WA = N \times TS / \rho A - (TS + RT)$$

$$WB = N \times TS - (TS + RT), \text{ if } \text{neg set} = 0$$

$$WS = WP \times STS/TS + 2 \times WA \times (1 - STS/TS) \times SRT/RT + WB \times (1 - STS/TS) \times (1 - 2 \times SRT/RT)$$

APPENDIX II

Notations

Same as under Appendix I.

M : Number of parallel servers

H : Average number of occupied servers

ρP : H/M

TS, RT, N, M

$$H = \left[1 + \sum_{n=1}^N \prod_{i=1}^n \{(N-i+1) \times k/m\} \right]^{-1} \times$$

$$\left[\sum_{n=1}^N m \times \prod_{i=1}^n \{(N-i+1) \times k/m\} \right]$$

when $1 \leq n \leq M-1$ then $m = n$

when $M \leq n \leq N$ then $m = M$

$$WP = N \times TS / (\rho P \times M) - (TS + RT)$$

APPENDIX III

Notations same as under Appendix II.

1. Calculate by means of procedure under Appendix I.

WP, WA, WB , and WS using a number of clients equal to N/M .

2. Calculate a correction factor.

$$CF = WS/WP$$

3. Apply this correction factor to the WP calculated using the procedure under Appendix II.

$$WS(N) = WP \times CF$$

6.6 Reclamation

6.6.1 Introduction

LEE W. SAPERSTEIN

By the nature of reserve exhaustion, surface mining is a temporal use of the land surface. The time span of mining can be blinkingly short as in a borrow pit for road building material or seemingly eternal as in some of the massive open pits for copper. Nonetheless, inherent in the nature of the mining process is the fact that there will be a time when mining ceases. Consequently, good mine design and good mining practice require that attention be paid to the postmining use of the land formerly used by a mine. In this section, *reclamation* is defined as those operations that prepare mined land for postmining use. Reclamation also includes those steps that stabilize mined land in an environmental sense. Hence, reclamation is integral to a total plan for erosion and sediment control. Reclamation is not a single step supplementing mining, rather it is a series of integrated operations that begins with initial mine planning, continues through the extraction phase, and does not end until the new, postmining land use begins.

The emphasis of this section is on reclamation in active mining. The methods described are, of course, applicable to the reclamation of other disturbed lands such as refuse and waste piles or tailings dams. Many of the methods have been developed and tested during the reclamation of previously abandoned (derelict or orphan) mined lands. Although a rigid distinction is not made here between the reclamation of active and abandoned mine lands, note is made that others may do so. In British terminology (Down and Stocks), *restoration* means the return of newly mined land to postmining productivity, whereas *reclamation* means the recovery of derelict land (abandoned industrial land including that from mining) to usefulness. American usage of the word restoration has caused it to mean a strict replication of conditions existing before mining.

The operations of reclamation depend upon those applied scientific disciplines that make up the environmental sciences. They include soil mechanics for ground stability, soil science for soil productivity, hydrology and geohydrology for surface and ground water flows, agronomy for revegetation, ecology for baseline studies, and the social sciences for land-use planning. This section includes a review of those parts of the foregoing subjects necessary for good reclamation. Hydrology and geohydrology are treated in separate sections because they apply as well to considerations in mining other than reclamation.

Methods of reclamation have improved and there has been a substantial growth in their application in a relatively short period of time. Concurrent with this growth has been a substantial increase in reference literature. The bibliography in this section includes many general references that give a more extensive treatment of the subject than is possible here. The Office of Surface Mining (OSM) is charged with maintaining an information repository on surface mining. Infor-

mation is retrieved from the repository by use of the SEAM system (USDI).

6.6.2 Reclamation Planning

RAJA V. RAMANI, RICHARD J. SWEIGARD, AND MICHAEL L. CLAR

INTRODUCTION

Mining, in its various forms, has utilized 2.31 Mha (5.7 million acres) of land in the United States from 1930 through 1980. This represents 0.25% of the nation's total land area, far less than the amount of land devoted to any other use such as agriculture, urban development, national parks, wildlife refuges, forest service wilderness, or highways. Of the total area affected by mining, 47% has been reclaimed by the mining industry meaning that approximately 0.13% of the nation's land area is currently being used by the mineral industries, has been abandoned, or has been reclaimed by some organization other than the mine operator (Johnson and Paone, 1982).

Land disturbance by the mining industry can be classified in several ways. Two useful classifications involve (1) mineral commodities and (2) mining functions. From Fig. 1 (commodity distribution) it is apparent that coal mining is by far the largest land user in the mining industry. In Fig. 2 (functional distribution), the affected total land area is classified according to mining function. Surface mining is responsible for 85% of the total land utilized. Underground mining accounts for a relatively small percentage (5%). Mineral processing wastes occupy the remaining (10%) of the land (Johnson and Paone, 1982). Therefore, a large component of the efforts in reclamation planning, research, and regulatory controls is directed toward surface mining, particularly the surface mining of coal.

Since one of the primary goals of reclamation is to restore the land-use capability to disturbed land, reclamation plan-

ning is necessarily related to land-use planning. The scope of this section, therefore, goes beyond the strict sense of reclamation plan preparation as mandated by some federal and state legislative acts and addresses mineral resource utilization in conjunction with renewable resource conservation. The term *reclamation planning*, as used in this section, encompasses the consideration of natural and cultural factors that impact land use, economic and technical feasibility of reclamation plans, mining methods, and current planning processes employed by the mining industry and the public sector.

LEGAL BACKGROUND

Concern on government's part for effective reclamation of mined land has been evidenced through the years in both the passage of regulations and increased research and development efforts. Prior to 1965, only seven states had specific laws requiring postmining land reclamation. The first state surface mine reclamation act was adopted by West Virginia in 1939 followed by Indiana (1941), Illinois (1943), Pennsylvania (1945), and Ohio (1947). By 1977, when the Federal Surface Mining Control and Reclamation Act was passed, 31 of the 37 states with coal surface mining operations were exercising some degree of control over those operations. The first state laws basically addressed limited grading and revegetation of spoil piles. Over the years, more comprehensive state laws evolved through modifications and amendments to existing legislation. In the 1950s and 1960s, the laws were modified to include stricter grading requirements, soil con-

Fig. 1. Percentage of land used by selected commodity, 1930-1980 (Johnson and Paone, 1982).

Fig. 2. Percentage of land used by mining function, 1930-1980 (Johnson and Paone, 1982).

servation measures, and water quality control. Modifications in the late 1960s and 1970s went beyond simple reclamation standards to the control of all major activities before, during, and after mining. Not all state programs addressed each of the major areas of concern. In addition, the levels of control on the same area varied from state to state. States with a long history of surface mine regulation had developed the most comprehensive and detailed regulatory programs.

By the early 1970s, it became clear that surface mining of coal would come under increasing scrutiny on environmental matters. The move was already underway to enact federal legislation (Imhoff, Friz, and LaFevers, 1976). In 1977, after nearly ten years of legislative efforts and three presidential vetoes, the federal government took a major step to standardize public policy with the passage of the Surface Mining Control and Reclamation Act (PL 95-87), hereafter referred to as the 1977 Act. Although the gradual evolution of various state laws and regulations had an impact on surface mine planning and design, PL 95-87 had immediate and far-reaching effects. With objectives of eliminating the detrimental effects that unequal standards had on interstate commerce and of providing adequate protection of all natural resources, the federal government implemented a plan that included, among other provisions, minimum performance standards and comprehensive data requirements for mining permit applications. This action has had many direct and indirect impacts on surface mine planning and design. It has also affected the way mining companies organize to perform these new or expanded functions.

The legal authority for regulating surface mine reclamation and for controlling land-use decisions originated and developed along different lines. The primary objective of surface mine reclamation is to preserve or restore the pre-mining land-use capabilities. On the other hand, the general goal of land-use planning, as conducted by the public sector, is to protect the health, morality, and well being of the public. This is generally done through the formulation of plans that are intended to guide development, conserve resources, and prevent hazardous or conflicting uses of the land. Although the overall goals may differ, the relationship between surface mine reclamation and land-use planning becomes apparent when decisions must be made concerning the use of reclaimed surface-mined land. The jurisdiction over these matters can become confusing, particularly since it involves both public and private interests. A detailed review of the public policy or its impacts on reclamation planning is beyond the scope of this chapter. The following is abstracted from an expanded discussion by Ramani and Sweigard (1983).

The formulation of land-use plans and the imposition of land-use controls is considered to be a right of each state. Most states have, however, passed this authority to the local governments. Eleven states, however, have returned some form of control back to the central state government. This right does not apply to federal land. The Federal Land Policy and Management Act of 1976 required the Bureau of Land Management to prepare comprehensive plans for the management of all public lands. Attempts in the past to institute a national land-use policy, or even to pass legislation that might pressure states to require comprehensive planning affecting private land, have not been successful. Although the federal government has ostensibly avoided any land-use planning legislation that would interfere with privately owned land, the impact of several environmental bills on land-use planning is apparent. There exists a great amount of control on land development and management through a complex maze of federal, state, and local laws pertaining to air, water,

solid waste, wilderness preservation, wildlife protection, etc. (Office of Technology Assessment, 1979). As an example, in Fig. 3 the effect on the environment from each operation in coal mining and handling is illustrated. Federal legislation addressing each of these impacts is indicated in Fig. 4. A listing of agencies involved in the review and issuance of permits for surface coal mining operations is given in Table 1. Clearly, the move is toward some form of a common system of land-use planning and land development with participation from local, state, regional, and federal agencies.

The 1977 Act was concerned principally with the surface mining of coal. Surface mining of noncoal minerals is generally regulated under a variety of legislation on health and safety, environmental pollution control, and natural resource conservation at the federal and state level (COSMAR, 1979). Local authorities regulate surface mining through land-use controls that provide for public and professional participation, action, and enforcement (Curry and Fox, 1978). It is clear, however, that procedures mandated by the 1977 Act for coal will affect the attitudes of regulatory agencies toward the mining of noncoal minerals.

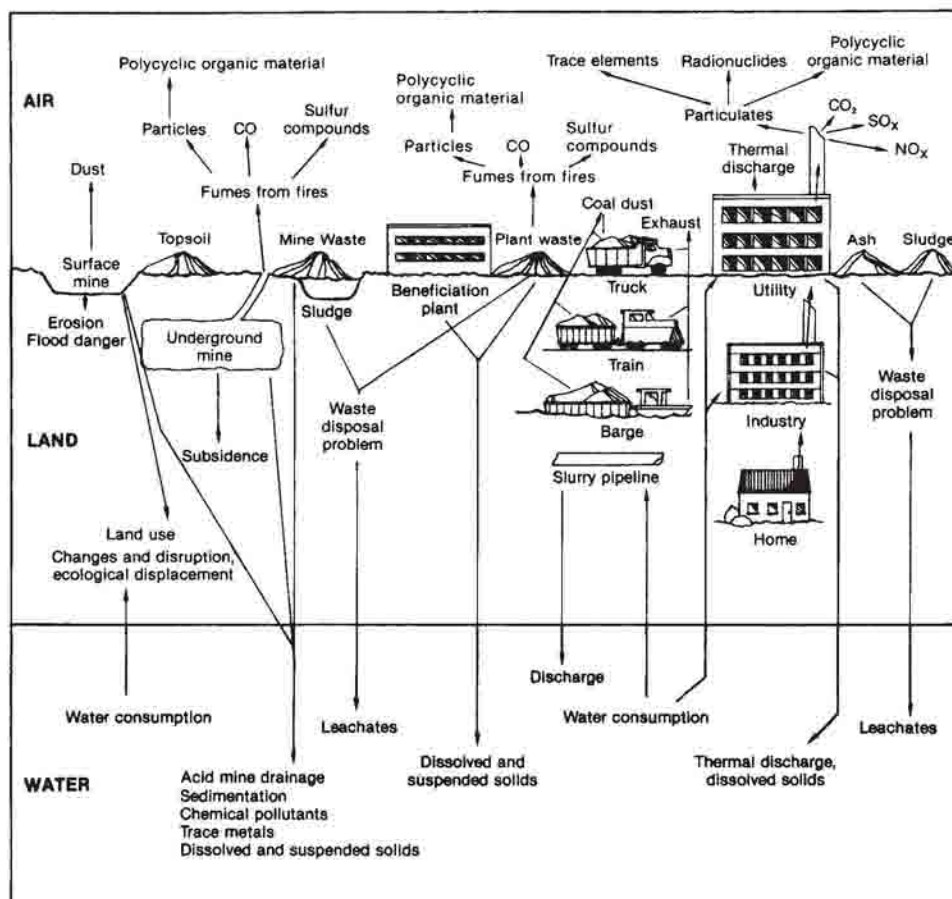

RECLAMATION PLAN

Several provisions of the 1977 Act and the regulations promulgated thereunder deal with the protection of the environment from surface mining damages. Two sections of the 1977 Act are important from reclamation and land-use planning aspects. Section 508—Reclamation Plan Requirements—is intended to ensure that there will be an approved postmining land use plan for the mined area. Section 522—Designating Areas Unsuitable for Surface Coal Mining—is to withdraw areas from surface mining. Specifically with regard to obtaining a mining permit, a reclamation plan must be submitted that shall be of such a detail to demonstrate that reclamation can be achieved as required by federal or state programs. The various components that are required by law in the reclamation and operations plan are listed in Table 2. Such a plan must cover, among other aspects, the following important points with regard to the uses of land:

- 1) The uses existing at the time of the application, and if the land has a history of previous mining, the uses that preceded any mining.
- 2) The capability of the land prior to any mining to support a variety of uses, giving consideration to soil and foundation characteristics, topography, and vegetative cover.
- 3) The use that is proposed to be made of the land following reclamation, including a discussion of the utility and capacity of the reclaimed land to support a variety of alternative uses and the relationship of such use to existing land-use policies and plans, and the comments of any owner of the surface, state, and local governments, or agencies thereof that would have to initiate, implement, approve, or authorize the proposed use of the land following reclamation.
- 4) A detailed description of how the proposed postmining land use is to be achieved and the necessary support activities that may be needed to achieve the proposed land use.
- 5) The consideration that has been given to making the surface mining and reclamation operations consistent with surface owner plans, and applicable state and local land-use plans and programs.
- 6) The consideration that has been given to developing the reclamation plan in a manner consistent with local physical, environmental, and climatological conditions.

The requirement that companies must submit a reclamation plan is not new. However, that surface mine planners

Fig. 3. Effects of coal-related activities on air, water, and land resources (Office of Technology Assessment, 1979).

must investigate "the utility and capacity of the reclaimed land to support a variety of alternative uses" [PL 95-87, Sec. 502(a)(8)] was not a requirement in most state laws. It is beyond the scope of traditional reclamation planning and enters into the area of environmental site planning or land-use planning. This provision of the law requires additional expertise in and the inclusion of many disciplines in the mine planning process.

In short, the planning of surface mines in general, and specifically that of reclamation and postmining uses of land has become very complex. Premining definition of long-range land-use plans for minable lands makes it possible to minimize any disturbance of the land that is not part of the normal mining or land-use plans and to limit reclamation activities to those required by the future-use plans. The integrated mining, reclamation, and land-use planning diagram, Fig. 5, defines information flow and interactions that should take place for the evaluation of mining, reclamation, and land-use plans before a mining plan is put into practice. The loops through which the mining and reclamation plans have to pass include not only federal, state, and local agencies, but special interest groups and the general public. The planning of surface mines thus is very involved and must be very thorough, with preserving or enhancing the long-term use of the land as a major objective. The application of an integrated mining, reclamation, and land-use planning concept requires an analysis of the interactions that must take place between the various levels of land-use planners. The development of procedures to evaluate land-use alternatives is also required (Ramani, 1978).

CURRENT RECLAMATION PRACTICES

Rehabilitation of surface-mined land is being accomplished through the systematic application of reclamation technology. Spoil banks that can be revegetated present minor problems and have great potential for development. Various reclamation programs that are being actively pursued include restoring the ground for agricultural and livestock farming, reforestation, recreation, and housing and industrial sites (Ramani, et al., 1977; Ramani and Grim, 1978). The possibilities for development under these conditions are limited only by cost-benefit consideration. Examples of reclaimed lands are shown in Figs. 6 through 10. There are, however, marginal and problem spoils (acid, toxic, etc.) requiring special attention and additional planning. Concern for good mining practices and effective land reclamation programs is evidenced in both the passage of regulations and increased research and development efforts. The various unit operations of reclamation are discussed elsewhere in this chapter; however, a time sequence of reclamation activities for surface coal mining is given in Table 3. This time sequence provides an orderly approach to grading, soil handling and stabilization, revegetation, and hydrologic control, all necessary for returning surface-mined land to productive uses.

PREMINING PLANNING

The planning problem with regard to surface mining is one of maximizing production and maintaining environmental quality, consistent with the constraints imposed by the regulatory agencies and the need to satisfy the profit objec-

tives of the companies. In the 1970s, several research projects were initiated to aid in the premining planning of surface coal mining (Grim and Hill, 1974; Dames and Moore, 1976; Imhoff, et al., 1977; Ramani and Clar, 1978; Pugilese, et al., 1979). Mining actions use up some resources to produce minerals. The mining process, along with processes both upstream and downstream from mining, produce waste products; all these affect the environment. There are direct costs and revenues to the company and public from mining. Also, there are indirect costs and benefits. All these must be rec-

ognized and coordinated in the premining planning process. The necessary planning steps are to (1) make an inventory of the premining conditions; (2) evaluate and decide on the postmining requirements of the region, consistent with the needs and desires of the affected groups; (3) analyze alternative mining and reclamation schemes to achieve best the objectives; and (4) develop an acceptable mining, reclamation, and land use scheme that is the most suitable under the technical, social, and economic conditions (Ramani, et al., 1977; Riddle and Saperstein, 1978).

Information Needs

For planning reclamation, information is needed in several areas. The initial concern from the environmental standpoint was the ability to reclaim the land in a minimal manner; today, however, the environmental studies required prior to opening surface mines are much more detailed. Any attempt to extract mineral resources involves consideration of physical, biological, social, physiosocial, biosocial, and psychosocial factors of the mining environment. From the initial construction of access facilities for prospecting to the final completion of the mining and beneficiation operations, the ecosystem balance is continually being altered.

Since the ultimate goal of the reclamation plan is to ensure that the surface-mined land is returned to a productive use, it is appropriate to consider information needs for postmining land-use planning. Land-use factors can either be classified as natural or cultural. Important factors that must be considered are listed in Table 4. A brief discussion of the major factors follows. Detailed discussion of these factors can be found in Clar (1982), Clar and Ramani (in press), and Ramani and Sweigard (1983).

Natural Factors

Natural land-use factors include, at least, the geomorphic, climatic, hydrologic, and soil characteristics of a site. Although these characteristics can be altered by man, they were initially the result of nature.

Topography: Topographic relief is the difference in elevation between high and low points in a specific site or region. Relief and its relationships to climate, soils, hydrology, and plants are of concern to mine planners. The configuration or topographic relief of the land surface, the direction in trends of mountain chains, and the proximity to large water bodies must be considered together since these factors largely determine the direction of prevailing winds, humidity of the atmosphere, and amount of precipitation. Slope or gradient affects runoff and drainage, hence, water content of the soil (Toumey and Korstian, 1947). Topography influences the selection of the type of mining and mining equipment. Severe terrains also influence the methods of revegetation, and limit alternatives for future land use.

Climate: Extremes in climate affect the selection of equipment. Seasonal fluctuations determine desirable planting pe-

Fig. 10. Water-based recreational use of reclaimed area mine.

Table 3. Time Sequence for Reclamation Activities

-
- I. During site preparation:
 - 1. Install control measures (diversion, sediment traps and basins, etc.).
 - 2. Clear and grub, marketing lumber if possible; stockpile brush for use as filters; run brush through woodchipper and use chips for mulch.
 - 3. Stabilize areas around temporary facilities such as maintenance yard, power station, and supply area.
 - II. During overburden removal:
 - 1. Divert water away from and around active mining areas.
 - 2. Remove topsoil and store it if possible and/or necessary.
 - 3. Selectively mine and place overburden strata if possible and/or necessary.
 - III. During coal removal:
 - 1. Remove all coal insofar as possible.
 - 2. For the purpose of controlling postmining ground-water flows, break, or conversely prevent damage to, the strata immediately below the coal seam as desired.
 - IV. Immediately after coal removal:
 - 1. Seal the high wall if necessary.
 - 2. Seal the low wall if necessary.
 - 3. Backfill—bury toxic materials and boulders, dispose of waste, ensure compaction.
 - V. Shortly after coal removal:
 - 1. Rough grade and contour, taking these factors into consideration:
 - a. Time of grading—specific time limit; tied to advance of mining; seasonal considerations.
 - b. Slope steepness.
 - c. Length of uninterrupted slope.
 - d. Compaction.
 - e. Reconstruction of underground and surface drainage patterns.
 - 2. If necessary, make mine spoil amendments (root zone), taking these factors into consideration:
 - a. Type of amendment—fertilizers, limestone, fly ash, sewage sludge, or others.
 - b. Depth of application.
 - c. Top layer considerations—temperature (color), water retention (size consist, organics), mulching, and tacking.
 - VI. Immediately prior to first planting season:
 - 1. Fine-grade and spread topsoil, taking seasonal fluctuations into consideration.
 - 2. If necessary, manipulate the soil mechanically by ripping, furrowing, deep-chiseling or harrowing, or constructing dozer basins.
 - 3. Mulch and tack.
 - VII. During the first planting season:

Seed and revegetate, considering time and methods of seeding, choice of grasses and legumes.
 - VIII. At regular, frequent intervals:

Monitor and control—slope stability; water quality, both chemical (Ph, etc.) and physical (sediment); vegetation growth.
-

Source: Ramani, 1978.

riods. In addition to the problem of permafrost in severely cold climates, operation of mobile equipment becomes difficult. Heavy rains can cause erosion, complicating maintenance of water quality control and establishment of vegetation.

Temperature acts as a constraint, particularly to agricultural and silvicultural land uses. Cyclic and seasonal changes in temperature determine the length of the growing season, potential evapotranspiration, precipitation occurring as snow, and frequency of freezing and thawing. These conditions are of prime concern for agricultural purposes, particularly, plant growth. A high freeze-thaw frequency accelerates weathering of overburden materials, increasing the infiltration characteristics of the materials.

Precipitation interacts with several other factors includ-

ing atmospheric pressure, temperature, solar radiation, wind, humidity, evaporation, and the geology and geomorphology of an area. These interactions determine the potential for water resource availability, a major factor in determining the potential of an area for resource development. A water supply deficiency, such as that encountered in the arid regions, not only makes reclamation of mined lands difficult but may preclude any type of postmining development. In the humid regions, the situation is reversed. Here excessive rainfall can represent major design problems.

Altitude: Altitude, the height above sea level, has a pronounced effect on the climatic characteristics of a site. The atmosphere is less dense at higher altitudes and consequently is incapable of absorbing and retaining as much heat as is retained at lower altitudes. A rise of 91 m (300 ft) in altitude

results in a fall of -17°C (1°F) in temperature. This decrease in temperature largely accounts for the greater amount of precipitation on the windward side of mountains, ridges, or hills. The lowering of temperature, however, is greatly modified by the configuration of the land and by the air currents. Valleys, coves, and ravines may be more exposed to danger from frost than the adjacent slopes several hundred meters (feet) higher in elevation (Toumey and Korstian, 1947).

Exposure: Exposure or aspect refers to the direction of the slope of the land with respect to the points of a compass. The aspect of a slope interacts closely with altitude and slope angle to determine the amount of sunlight received by a site. Sunlight, in turn, modifies the moisture content and the temperature of the soil and air. A northern slope is considerably more moist and cooler than a southern slope. Exposure

influences plant growth chiefly through its impact upon temperature and soil water. Thus a slope exposed to the sun and wind often bears a different vegetation from one less exposed to either. Great differences may exist in temperature and atmospheric humidity on different exposures only short distances apart (Clar, 1982).

Hydrology: Hydrology, both surface and underground, is important for any reclamation program planning. A knowledge of water movement and quality in the mine area and its modification during mining is essential. In all cases erosion and sediment production are immediate concerns in the critical postmining, revegetation time period, although their control during storms is a long-term problem that requires detailed planning.

Drainage systems are a complex component of the natural

environment and one that greatly influences the land-use suitability of a site. An analysis of an existing drainage system requires at least some understanding of stream course delineation, drainage basin delineation, the type of drainage pattern, drainage texture, slope, landform, and the ground water flow pattern. Drainage system analysis also adds to the understanding of basic bedrock structure and discontinuity patterns (Stranberg, 1967).

Surface mining operations create a significant impact on the drainage system. They necessitate the complete restructuring of the surficial and bedrock geology down to and slightly below the coal seam. Blasting and fragmentation of the consolidated strata and the spoiling sequence employed can result in substantial changes in numerous elements of the drainage systems. These generally include changes in the infiltration capacity of the surface soil and in the permeability, porosity, and conductivity of the subsoil and bedrock materials, and in the geochemical processes at work in these materials. Variations in the characteristics of these fundamental properties can result in marked changes in drainage patterns, watershed boundaries, and the availability of water supplies.

Geology: Geological aspects of the mineral occurrence (e.g., attitude, depth, thickness, stratigraphy, etc.) are the basis for establishing alternative mining and reclamation schemes, including slope stability. The nature of the overburden, especially those components such as sulfur that have potential environmental impacts, must be studied. The structural and stratigraphic evaluations affecting the hydrological conditions are critical for effective mining and reclamation. These conditions may impose limitations on potential land uses and may dictate that special reclamation practices be employed.

Soils: The identification of the material to be classified as topsoil is essential for their proper removal, storage, and postmining disposition. The characteristics of topsoil should be such that it ensures an effective growth of vegetative cover. Topsoil and subsoil, though not always the most ideal materials for supporting growth, do have certain advantages over other materials, including higher organic matter, better moisture-holding capacity, natural seed source, and ample soil microorganisms. The removal and storage of topsoil and

replacement of it on top of the graded spoil, in many instances, leads to better revegetation potential that, in turn, leads to better erosion control. In many older mining districts, spoil banks are only sparsely revegetated. This is due in part to the lack of nutrients in the spoil and the water flow characteristics of the restored strata. In cases where bedrock material, shale, sandstone, siltstone, and fireclay have been mixed with the original topsoil covering, inadequate fine-grained matrix material and organic matter may be available to provide nutrients or moisture-holding capacity. Too frequently, the fine-grained material sinks through the interstices in the coarse matrix. High infiltration capacity, high porosity, and high permeability are too commonly encountered when no attempt is made at top layer restoration and compaction. Color of the spoil has an effect on the surface temperatures of the spoil banks. Temperatures in excess of 66°C (150°F) have been reported on spoil surfaces composed of dark shales.

Summary: Natural land-use factors generally have a greater influence on low intensity land uses than on higher intensity uses. Natural factors are particularly important to agricultural, forestry, wildlife, and recreational uses. An estimate of the relative importance of each natural factor in determining land-use suitability is given in Table 5.

Cultural Factors

Cultural factors include all of those geographic, demographic, and economic characteristics that are the result of man's activities.

Location: Geographic location establishes the proximity to population centers and developed facilities, such as transportation systems, power supply, labor pool, manufacturing and supply services, and shops. All of these, if available, enhance the attractiveness of the site. The proximity to cities also increases the potential of the site for intensive postmining use. However, proximity to urban centers can also be an obstacle to new surface mine development due to adverse public pressure.

Accessibility: The value of a parcel of land is directly related to the ease or difficulty of access to roads and streets and the availability of transportation facilities as well as other utilities, including water and gas mains, sewers, and electrical

Table 5. Relative Importance of Natural Factors* as Determinants of Land Use Suitability

3 = Factor has low degree of influence.

and telephone lines. In addition, other services such as mail delivery; police and fire protection; and garbage, trash, and snow removal are significant (Weimer and Hoyt, 1966). The accessibility of a site is often measured by two parameters: travel distance and travel time.

Surface mining operations generally increase the accessibility of a given site. This increase is due to the addition of haul roads necessary for hauling the mined product to the markets or preparation plant for further processing. Sometimes rail lines are provided that may be restricted to onsite operations or that may provide a spur to a trunk line. It is also common to provide electric and telephone lines to the site. All of these positive aspects of the mining operations should be recognized (Clar and Ramani, in press).

Size and Shape of the Site: Size is an important factor in determining land use, and use in turn has a very direct bearing on income production. Size also determines effectiveness of use; a case in point is the trend toward larger farms as agriculture becomes more highly mechanized. Value, of course, is not directly proportional to size. Up to a point, additions to the size of a parcel of land tend to increase its income-producing capability and hence its value; thereafter, such additions tend to be of diminishing importance.

The shape of the land parcel may determine the possible uses to which it may be put and hence affect its income-producing capability. While lots or irregular shapes may be used to advantage for residential purposes, regularity is usually desirable for business, industrial, or agricultural uses.

Surface mine sites exhibit a great deal of variation in size and shape. They can vary in size from 4 to 6 ha (10 to 15 acres) of annual disturbance for a small operation to a range of from 120 to 200 ha (300 to 500 acres) of annual disturbance for large area mines. The shape of the site is also related to the type of mining system used. This is particularly true for contour mining operations that result in long, narrow strips of reclaimed land.

Surrounding Land Use: The status of the neighboring land, particularly with respect to type and intensity of use, and future trends has a strong influence on the suitability of the mine land to support various activities. In general, the use adopted at any specific site should be compatible with surrounding uses in terms of views, prevailing winds, protective belts of planting, open space, noise, and access routes.

Postmining land-use plans must comply with any existing local land-use plans. Compliance with such plans, if they exist, will generally insure compatibility with surrounding land uses.

Land Ownership: Most surface mined lands are privately owned. In 1973 ownership of these lands was distributed as follows (USDA, 1973):

Type of ownership	%
Public ownership:	
Federal	5
State/local	4
Subtotal	9
Private ownership:	
Mining industry	52
Farm	23
Other	16
Subtotal	91
Total	100

Ownership of the land and of mineral resources can often provide a source of significant conflict. In many instances, the surface and mineral ownerships have been severed. Often the right to extract the mineral resources is contingent upon providing a postmining land-use plan that is acceptable to the owner of the surface rights (Clar and Ramani, in press). It has also been observed that mining companies are more likely to propose an alternative land use for company-owned land than for leased land.

Type and Intensity of Use: A US Department of Agriculture (USDA) survey of mine lands showed that many were scattered small acreages best treated as part of the total conservation management of the farm and other areas with which they are intermingled (USDA, 1973). Nearly 80% of the sites were in forest, farm, or grassland or were reverting to forest at the time of the survey. These same uses were being made of land adjacent to 86% of the sites. Less than 2% of the acreage land had been set aside solely as outdoor recreation or wildlife areas; usually these are compatible with other uses of the land.

Surface mining operations are seldom permitted adjacent to highly urbanized areas. Typically the surrounding land will be undeveloped or at best used for agriculture, silviculture, and related activities. It must be kept in mind, however, that the land use selected may in turn restrict the development potential of adjoining property. Communities within the mining regions should carefully study and map their patterns of growth and expansion and seek to develop land use control mechanisms to reduce the loss of valuable mineral resources to urban expansion. Loss of sand and gravel and building stone deposits due to preemptive land development is a common occurrence and must be avoided.

Population Characteristics: Population characteristics of the surrounding area are key factors in determining land-use suitability. This information is provided decennially by the US Census Bureau and local planning agencies often prepare updated estimates between censuses. Although the total population is important, the percent change in population over recent years is a more useful parameter. Growth is the primary force behind land-use change. For an alternative postmining land use to be feasible, there must be some growth in the area, particularly for high intensity land uses, such as community development. Other demographic parameters such as population density, average household size, age distribution, and household incomes are useful in planning for postmining land use.

Summary: Cultural factors have a greater influence over land-use suitability for higher intensity uses such as residential, institutional, commercial, and industrial uses. These uses are already related to the proximity of population centers, particularly to the demand for services and products from these institutions. An estimate of the relative importance of each cultural factor in determining land use suitability is shown in Table 6.

LAND-USE ANALYSIS

The current land-use patterns may provide the best guidelines for use after reclamation. For example, forested hillside land adjoining a pasture may be more desirable as a pasture after mining if the need is for pasture lands. Similarly, orphaned mined land in a wilderness area may be more useful if restored as a forest. Future land-use plans contrary to premining use are unusual and not the common practice. Acceptance of mountaintop removal and valley fill mining methods that create new flat areas in regions where such areas are in short supply reflect the permanent positive po-

tential of the temporary drastic disturbance of lands due to mining.

Identification of the current and probable future land uses can be summarized into the following five categories: (1) "wilderness" or unimproved use; (2) limited agriculture or recreation use with little development; (3) developed agriculture or recreation use such as for crop land, water sports, or vacation resorts; (4) suburban housing or light commercial and industrial use; and (5) urban housing or heavy commercial and industrial use.

Analysis of alternative long-term uses requires compliance with socioeconomic and public constraints as well as the economic goals of the mining company. Irrespective of the choice of short-term and long-term land use, the plans must be linked to the mining plan in space, time, and method. Definition of the long-range plans does achieve a purpose by minimizing disturbance unnecessary for the determined future use and limiting those reclamation activities that are not a part of the normal mining or land-use plans. Reference has already been made to the enactment of legislation at the federal and state levels pertaining to surface mining and reclamation. Mining companies today often have to meet

with nongovernmental, historical, wildlife, and other environmental groups to allay their concerns.

The integrated surface mining, reclamation, and land-use planning process illustrated in Fig. 5 requires delineation of the definitive tasks involved and identification of the locus of the responsibilities. In Fig. 11, two distinct land-use planning processes are recognized—comprehensive and site planning. The major tasks of each process are also identified. The respective roles of the public planners and the mining companies in these two processes are identified in Fig. 12. The site planning process itself is outlined in Fig. 13. In the site planning process, several feasible alternatives are to be evaluated through an iterative procedure applying social, economic, and environmental impact measurement techniques. This expanded portion of the detailed land-use planning process is illustrated in Fig. 14. Three case studies for reclamation and land-use planning for surface coal mines using the processes outlined in this section are reported by Ramani and Sweigard (1983). For the same mining area, there may be a number of feasible postmining land use alternatives. Also, since surface mining affords an opportunity to completely reshape the land forms, the potential for selectively

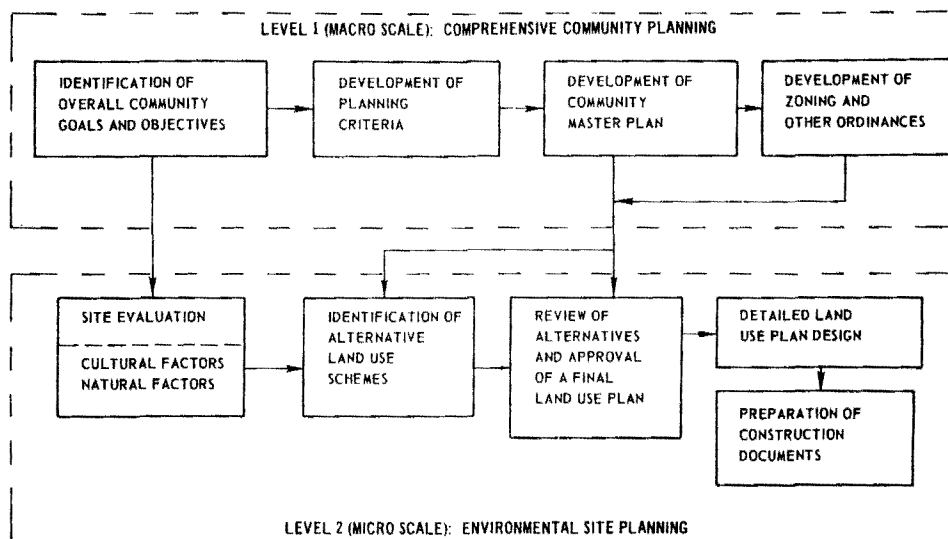

Fig. 11. Two levels of the land-use planning process.

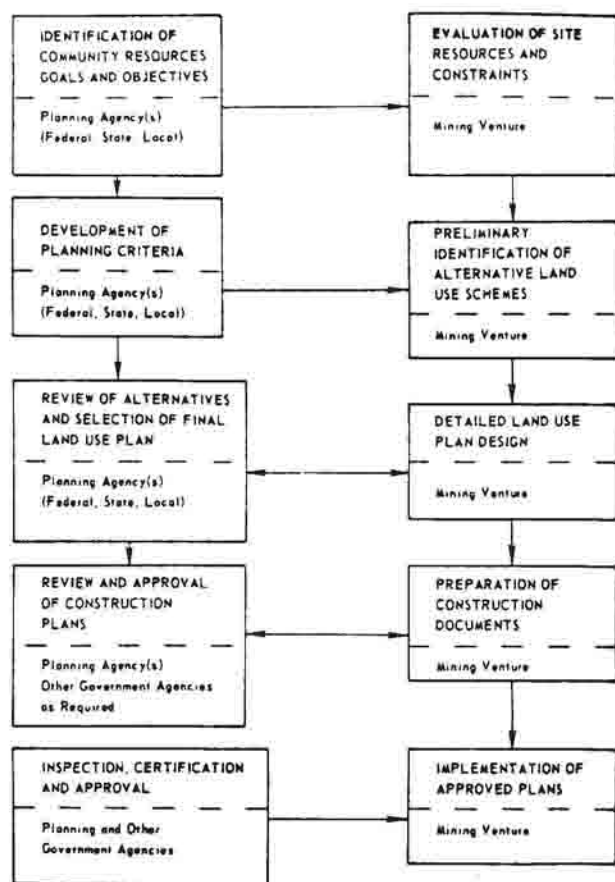

Fig. 12. Integrated public planning and mine planning.

reclaiming the land parcel for different end uses is great. Figs. 15, 16, and 17 show three different alternatives for reclamation and land-use development in a mining area. In practice, each plan will represent different amounts of earth-moving, grading, topsoiling, and vegetation planting for agricultural, wilderness, water and recreational, industrial, and residential uses.

The three case studies by Ramani and Sweigard (1983) indicate a general pattern of land-use planning and land management by the larger surface mine operators. In the formulation of postmining land-use plans, one of the most important factors is the postmining topography. Postmining topography is approximated by applying mine plan data, appropriate swell factors, and box and end cut locations to the premining topography. Another key factor is the location and thickness of high capability soils. This factor is particularly important in determining the location of agricultural lands. Location of property boundaries and public right-of-ways and limitations on certain equipment are also taken into consideration. For example, the grade limitation on mechanical tree planters may influence the location of forest land or the type of planting pattern that is employed. Premining land use, however, may play the most important role in determining the postmining land-use plan. Surface mine planners often endeavor to balance, as nearly as possible, the premining and postmining areas devoted to various land uses. Although the distribution of land among various uses may not change significantly, planning skills are required in designing a site plan that spatially orients the land uses in an efficient and aesthetically pleasing manner. Five primary postmining land-use designations are generally used: row crops, pasture/hay, forest, wildlife habitat, and water. Some additional land may be designated for public roads, etc. The planners may recognize a potential for higher intensity uses such as residential development or industrial uses; however,

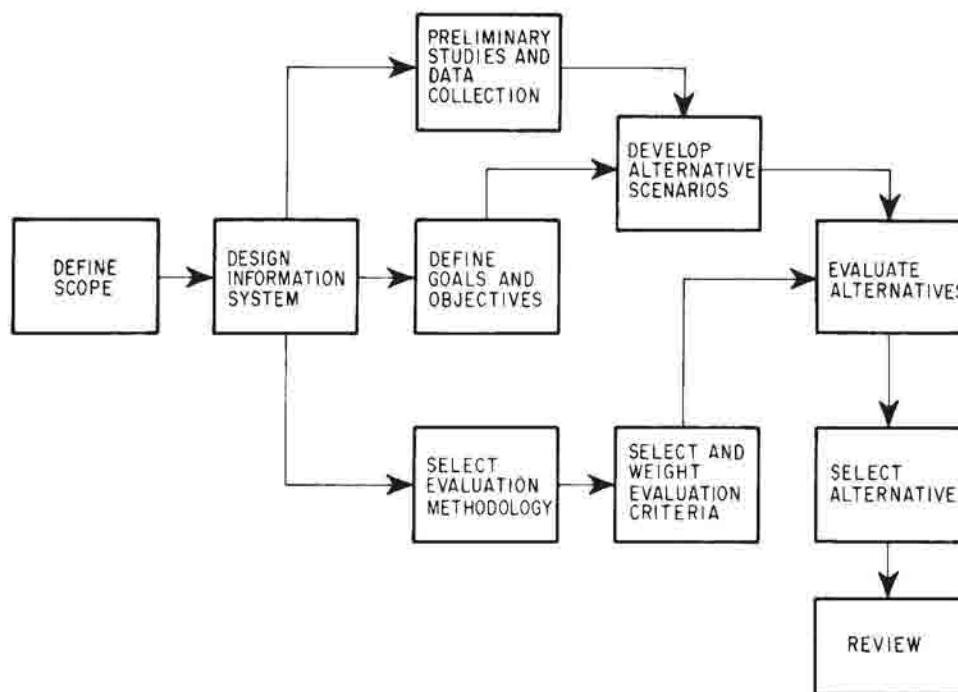

Fig. 13. Detailed site planning process for mined land.

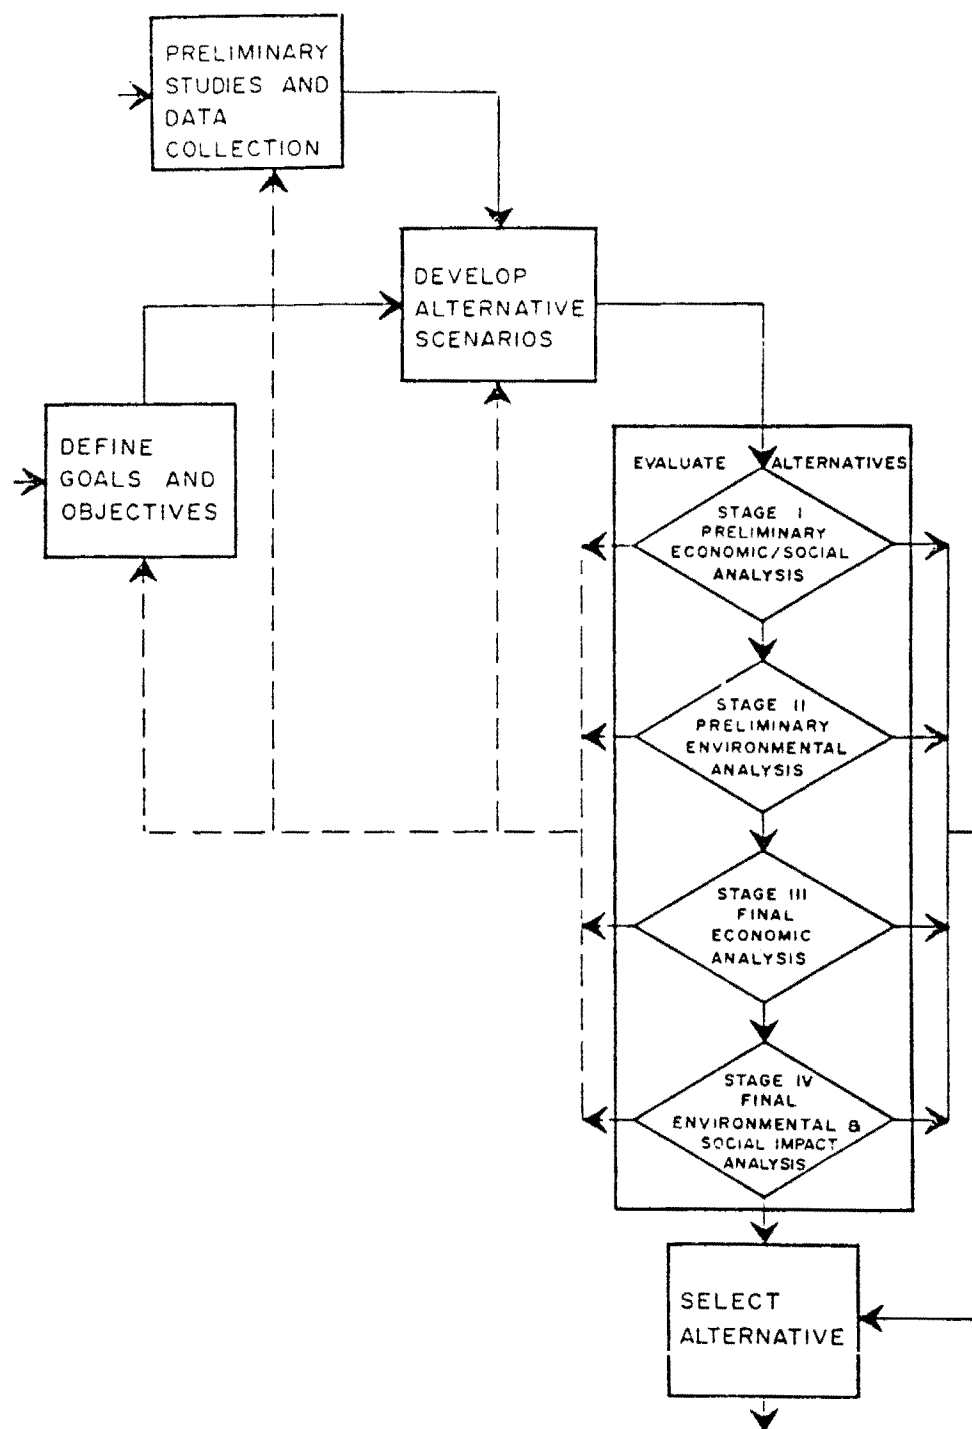

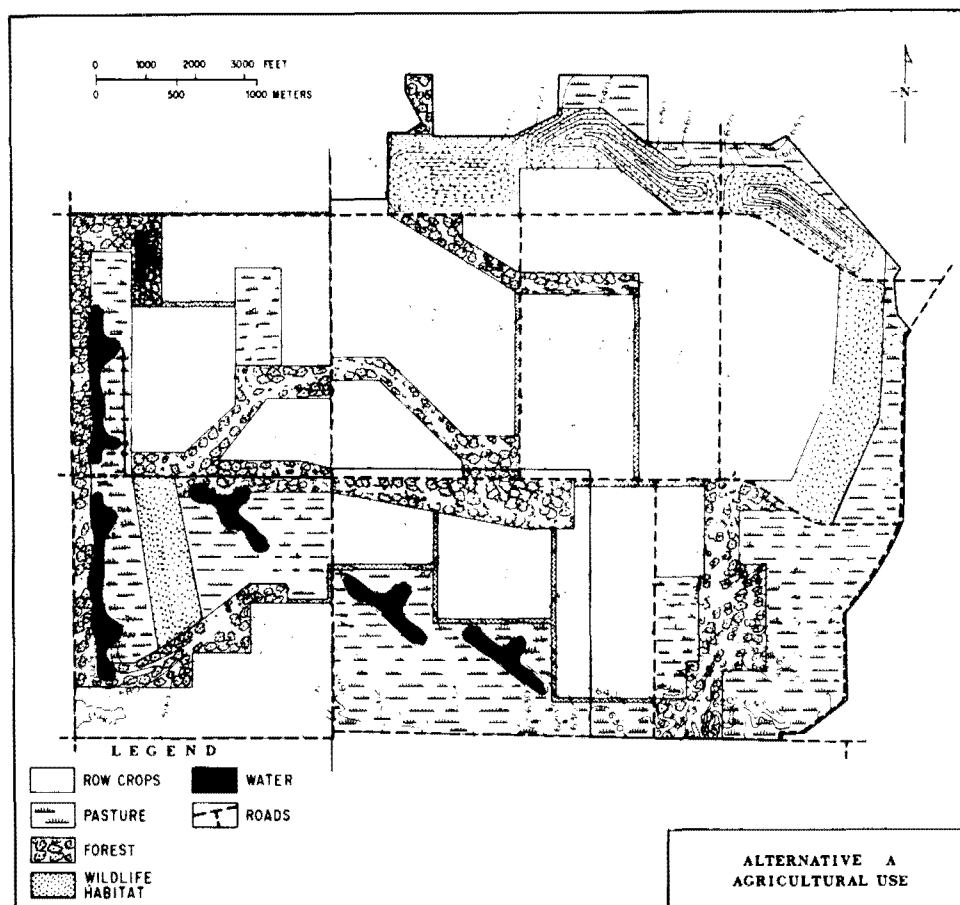

Fig. 14. Process for the evaluation of land-use alternatives.

these are not proposed as part of the required postmining land-use plan. Instead, the land is returned to one of the five primary uses until the bond has been released.

After all reclamation work has been completed, leased land is returned to the original owner. The company retains the right of access until the final bond release. Land that has been purchased by the company is generally retained for at least a few years. If possible, this land will be used for agricultural production. After a period of time, if it is de-

termined that the land is not needed for any future mining operations and is in fact a surplus, it may be considered for disposal. Disposal of surplus land is initiated by the land or real estate department. Before any land is sold or donated, input is solicited from the engineering department, the environmental engineering staff, the tax department, and the accounting department. After all of the necessary internal approvals have been obtained, the land is appraised and offered for sale.

Fig. 15. Agricultural use postmining land-use plan example for area surface mine.

ECONOMIC FEASIBILITY

In a free enterprise society, it is difficult to continue in business unless there is an adequate rate of return in monetary terms on the investment. The goals of environmental protection and mineral resource extraction therefore must be analyzed in terms of both the economic return and the constraints and incentives of the public and the government. At the mine level, it is necessary to establish the direct cash cost of reclamation.

Grim and Hill (1974) have summarized the results of several studies on reclamation costs for the surface mining of coal. In eastern Kentucky, reclamation costs have been estimated at about 8% of the total mining cost. Other cost figures in the literature vary from a low of \$500 to upwards of \$8000 per acre depending on the severity of the land effects and the reclamation requirements. Doyle and Chen (1973) have prepared a useful report on the analysis of pollution control costs. Their report addresses the costs involved in revegetation, acid mine drainage, stream diversion, strip mine spoil and waste, backfilling and regrading, etc.

Since reclamation costs are site-specific, the requirements of labor, equipment, and supplies for each site must be estimated. A convenient basis for estimation purposes may be identification of that volume of earth disturbed which must be contoured. The costs of reclamation are calculated for the disturbed land, and then assigned to the tons of coal or

mineral recovered. Reclamation costs are preferably indicated both in dollars per hectare and dollars per ton.

To minimize environmental disturbances and to maximize land use, it is necessary to include the sociohumanistic benefits and costs. These are not easily quantified, defy traditional engineering approach, and raise conflicts between the various organizations' objectives.

TECHNICAL AND ENVIRONMENTAL FEASIBILITY

Technical and environmental feasibility is a prime requisite for the adoption of any mining and reclamation plan. The scope of expertise required to complete these studies along with the necessary economic feasibility studies is outlined in Table 7. This list illustrates the complexities that may be involved in the coordination of the overall premining planning effort.

It is preferable to closely coordinate the reclamation plans with the mining plans since nonconcurrent reclamation methods tend to be environmentally less optimal and more expensive. Reclamation efforts initiated long after the mining activity has ceased generally serve a limited land use. Concurrent reclamation with positive controls aids in the development of well-conceived future land uses with a long-term program to finish and maintain the reclamation plans. Concurrent methods allow total spoil manipulation and/or com-

plete spoil profile construction (Stefanko, et al., 1973; Saperstein and Secor, 1973).

Mining Methods

Technical requirements of reclamation will vary depending upon the degree of restoration. In the standard surface mining approaches of today, selective replacement of material is relatively simple. Contour mining approaches such as block cut, box cut, haul back, mountaintop removal, and modified area mining are generally sufficiently flexible to allow segregation and selective replacement (Stefanko, et al., 1973; Saperstein and Secor, 1973; Grim and Hill, 1974; Ramani, et al., 1977). Larger scale area methods employing traditional overcasting are less flexible. However, selective placement of spoils in these cases can also be achieved by a combination of equipment and methods. For example, the requirement to save topsoil and spread it over the regraded land has led mining companies to use scrapers that remove the topsoil, run around the pit, and dump over formerly graded soil. Selection of shovel-truck systems, as opposed to conventional overcasting, also provides the needed flexibility in soil placement. In fact, the overburden conditions can be closely monitored, and the placement of the overburden achieved so as to ensure (1) burial of toxic spoils and less desirable material such as boulders or impermeable clays, (2) topsoil replacement, (3) desired stratigraphic sequence in the spoil, (4) flatter or other desired valley configurations, (5) desired quality of coal by blending in the pit, and (6) greater recovery of coal. The goal for premining planning and scheduling for

resource extraction and reclamation is to develop such steps as an integral part of the mining method.

Backfilling

In backfilling, three major areas of long-term concern are (1) slope stability, (2) ground-water control, and (3) water quality maintenance (Phelps, et al., 1981). The primary source of slope failure is the prolonged action of water through erosion and mass wasting. The primary result of water's actions on slopes is erosion and sediment production. Long uninterrupted slopes are undesirable as compared to ones with terraces and diversions that decrease slope lengths and direct runoff water to safe outlets. Additionally, while backfilling, the permeability of the fill for water percolation can be modified. Such modifications are achieved by sealing or leaving the coal seam open, and by selective placement of the spoil. One of the concerns of water quality control in addition to the acid potential is the sediment. The interconnection between slope stability and water quality (sediment) is enhanced by apparently conflicting approaches to these problems. Gross stability is enhanced by establishing grade and cover to minimize water infiltration and permeation. Conversely, erosion and sediment control are achieved by encouraging infiltration and permeation to minimize runoff. The proper approach would entail, first, the establishment of as heavy a cover crop after backfilling as possible to encourage vegetative interception and evapotranspiration as opposed to surface or subsurface runoff. However, not all of the water can be handled in this manner. Provision must be

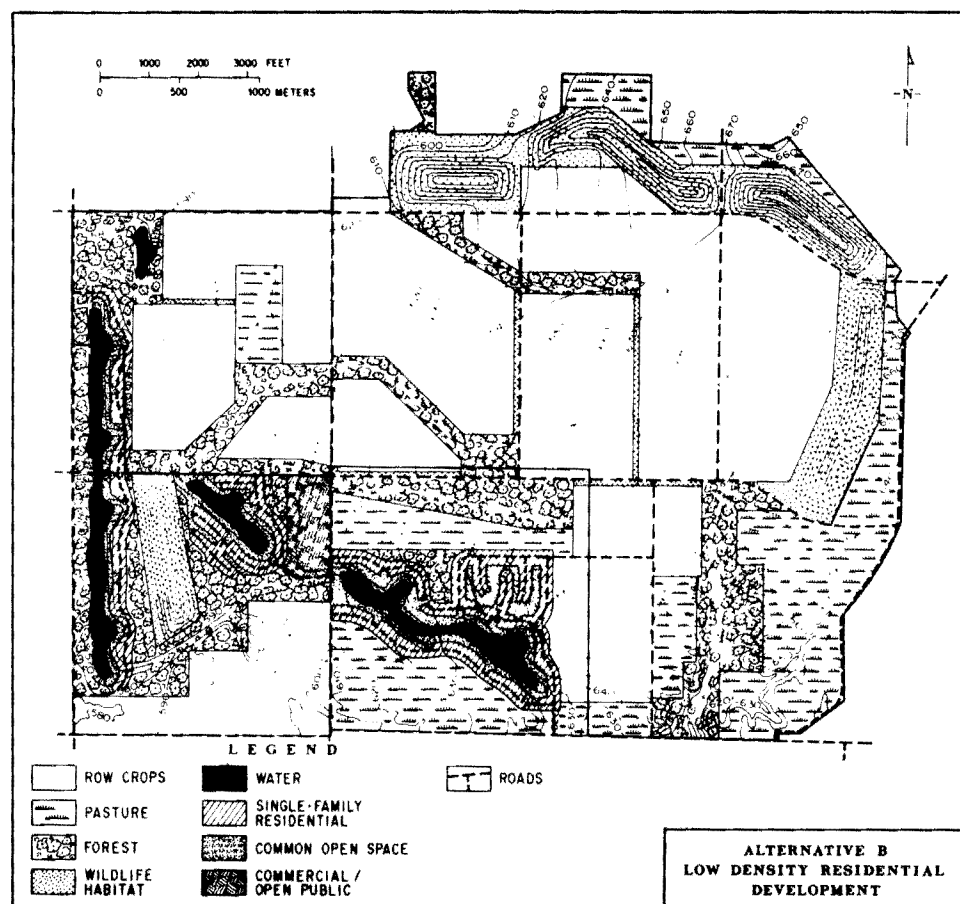

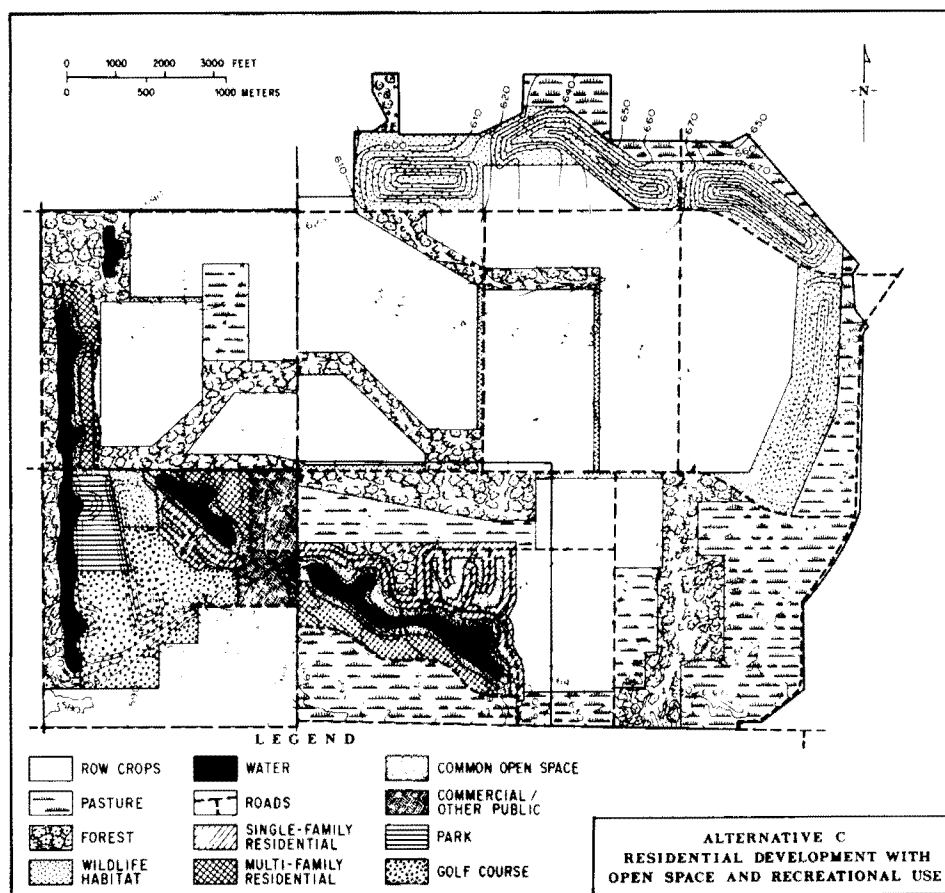

Fig. 16. Combined low-density residential use and agricultural use example for area mine.

Fig. 17. Postmining land-use example showing residential development with open space and recreational use.

made for storms by designing clean-running interceptions and diversions for excessive rainfall.

Stability and water quality are inherent in the design of fills and backfills. If a suitable, large-rock drainage base and contact zone is established at the base contact of the fill, slippage can be minimized while rapid drainage of ground water is enhanced. Such approaches of water quality and the control of stability are exemplified by the head-of-hollow or valley-fill concepts

Topsoil

Replacement of topsoil is practiced in mining where required by regulations. The dictum of topsoil replacement could be viewed as a requirement to replace or establish a layer of material of specific thickness, having certain physical and chemical characteristics and, primarily, capable of supporting some specific vegetation. In premining planning, attention is to be directed at identifying all strata potentially adaptable as such a surface covering.

Soil Amendments

Common approaches to soil amendments involve the addition of lime, fertilizer, and mulch as needed. Many mulches have been used to assist in establishing vegetative cover. Straw or hay can be manually applied, but they, as well as wood chips, are often spread mechanically or hydropneumatically. Mulches should be held in place with tar or chemical emulsion.

Fly ash and stabilized sewage sludge are other amendments which can add needed nutrients to reclaimed mined

land. However, use of these recycled amendments requires considerable testing and characterization of the material. For example, the composition of different fly ashes varies and some may prove toxic to plant growth. Also, care must be taken to avoid poisoning the soil with too high a level of heavy metals and salt from sewage sludge (Grim and Hill, 1974).

Revegetation

Rapid-growing, annual plants and small grains can be used to establish ground cover, to leave organic matter in the soil, and to serve as a mulch to assist the establishment of perennials. The common practice today is to establish such quick-cover mulch crops to assure vegetative stabilization and to enhance the organic content and water-holding capability of the surface layer. Scarification of the graded surface by furrowing or harrowing is also done to act as seed and water traps. Care must be taken in selecting species to avoid competition. Areas that are intended to remain as inactive grass cover must also be seeded with legumes to provide continuing nitrogen availability without the need for continuous, repetitive application of fertilizers. Certain water soluble ions such as aluminum and manganese may be especially toxic to some plant species.

MONITORING AND MAINTENANCE

Even with proper reclamation, rededication of the land for productive purposes may require lapse of additional time. Grazing, for example, should not be allowed immediately on a new cover crop. A careful plan of monitoring, control,

maintenance, and development is required before the land is totally restored.

Monitoring slopes to assure stability and control and to maintain water quality is very important. To minimize slope stability and water quality problems initially and to prevent them from occurring in the future, at the time of grading it is necessary to keep all surfaces as minimally sloped as pos-

sible. Additionally, through regular inspections, any failure or runoff must be corrected by refilling, compacting, and rapid establishment of cover. To control the erosion effects of flowing water, it is necessary to place interceptor and diversion channels to reduce down-slope flows.

Where coal mine drainage cannot be prevented, a long-term program to neutralize the discharge is necessary. In

Table 7. Areas of Technical Expertise Essential in Premining

Mine Planning Phase	Planning Activities	Areas of Specialization
Legal requirements analysis	Identification of regulatory constraints related to land use	*Land-use planner Attorney or paralegal specialist
Land and reserve acquisition	Prepare land use/land cover maps	Land-use planner Photogrammetrist/cartographer Plant biologist
	Prepare land ownership map	Photogrammetrist/cartographer Surveyor
Market development	Check market potential of site	Geographer Transportation engineer Land-use planner
Financial evaluation	Check if land development potential of the site will justify reclamation to a higher, more costly land use	Engineering economist Land-use planner Real estate specialist Fiscal planner
Coal beneficiation studies and plant design	Determine the impact of waste disposal on the postmining uses of land	Mineral processing engineer Environmental engineer Agronomist Geologist Hydrogeologist
Environmental impact studies	Evaluate the impact mining will have on the site with respect to capability and productivity	Mining engineer Environmental engineer Agronomist Geologist Hydrogeologist Terrestrial ecologist Plant biologist Agricultural engineer Archeologist Land-use planner Social scientist
Preliminary mine planning	Preliminary identification of postmining land uses	Mining engineer Land-use planner Agronomist Engineering economist
Permits acquisition	Land use information and postmining land use plan	Land-use planner Environmental engineer Agronomist
Administrative detail analysis	Submitted/approval of final land use plan

most surface-mining situations, much of the necessary layout is present in sediment-control ponds. Limestone, lime, anhydrous ammonia (where no discharge to surface drainage is encountered), soda ash, sodium hydroxide, or other suitable neutralizing reagents are commonly used to treat acid mine drainage. However, isolation of toxic material and concurrent backfilling is probably the most desirable approach to minimization of acid formation problems.

One other aspect of maintenance involves the sediment and erosion control installations. With appropriate planning and no unusual storms, such maintenance of these features may be minimal. However, control structures may become clogged or filled, and should be cleared and cleaned when necessary.

SUMMARY

Reclamation, that primarily began as voluntary revegetation measures, has developed into a complex field encompassing economic, environmental, and social considerations and requiring significant planning effort. The evolution of surface mining regulations is partially responsible for this transition. Also, the recognition of surface mining as a temporary land use rather than a permanent land dedication has contributed to this development.

One of the most important steps in reclamation planning is data collection. Data collection by itself, however, is not enough. Rather, it is the careful analysis of the economic, technical, and environmental characteristics of the site and the mining operation that transform the data into useful information. The expansion of reclamation planning in scope and complexity has created a need for additional professionals in the mining industry to perform these necessary analyses.

Some efforts toward achieving the integration of mineral resource planning and land-use planning are underway (Ramani and Sweigard, 1982). A notable program is the US Geological Survey's Resource and Land Investigation (RALI) program. For example, the Missouri River Basin Commission along with the RALI program directed a project to help state and local planners develop data and methodology required to analyze problems associated with western coal and energy development (WCPAP, 1979). Another attempt at long-term planning with regard to mineral resources is the Model Mineral Reservation and Mine Zoning Ordinance prepared by the Wisconsin Geological and Natural History Survey (Preston, et al., 1974; Friz, 1975). This model code has dealt with problems of land-use planning but has not had wide acceptance because the resource characterization necessary to apply this type of code is generally lacking.

Demands on available lands will continue to increase due to the projected increase in population and industrial expansion. Though there is an upper limit on the available lands, the multi-use nature of the lands will make it possible to meet these demands. However, this will not happen without adequate planning. Land uses can be broadly categorized as nonrenewable and renewable. Lands with minable resources can be dedicated at some point in time to the extraction of resources. Such a dedication, however long-term, is only temporary because of the nonrenewable nature of the minable resources. Implied here is that the land will be available before and after mining for other uses. Planning for such lands must have the objective that, as far as practicable, no nonrenewable uses are preempted and no renewable uses are permanently destroyed.

6.6.3 Unit Operations of Reclamation

L. B. PHELPS

INTRODUCTION

The unit operations of reclamation are generally different for open pit and quarry mining and for strip mining. In open pit and quarry mining, they usually are (1) pit slope reduction, (2) pit slope stabilization, (3) vision barriers, and (4) management of permanent rock and waste dumps outside the mining area. In contrast, strip mining reclamation unit operations consist of (1) backfilling the pit, (2) leveling the backfill, (3) providing stable contoured outside waste dumps, (4) topsoil handling, and (5) revegetation. Each of these unit operations will be dealt with in the context of appropriate mining type.

OPEN PIT MINING

Major reclamation planning for open pit mines is centered around the design and construction of outside rock dumps, waste piles, heap leaching piles, tailings ponds, and to a much lesser extent the pit itself. In the management of rock and waste dumps, it is necessary to plan for permanent structures. As such, they will remain in place when mining ceases at the pit. Therefore, major factors to be considered in design for reclamation are also related to their operation. The dumps should be constructed at the head of valleys in zones where there is, at most, intermittent stream flow. Construction of the dumps in such locations minimizes their visual impact on the area and provides the minimum surface area to be stabilized and revegetated. Where it is not possible to construct the dumps in such valley heads, the dumps should be designed and shaped to blend in with the topography. By such blending, it is more cost effective to establish the level of revegetation and other requirements to provide a reclaimed mine area.

Waste dumps or piles should be designed for the life of the reserve. Experience shows us too many piles that have had to be moved because they were located, in the first instance, in what became an awkward place. Typical practice is to start dumps close to the pit and then spread them away from the pit. This, over time, can lead to land-use conflicts with growing communities. Where the potential for land-use conflicts exists, it may be preferable to locate initial waste disposal sites at the ultimate boundaries of the mine property and have them grow back toward the mine and away from the community. Properly designed, stabilized, and reclaimed piles can, in this manner, be added to the stock of developable land rather than subtracting from it.

Reclamation of the pit is generally taken as providing stable slopes and allowing the pit to fill with water.

QUARRY MINING

A quarry is a specialized open pit operated to extract construction materials. As such, it is often found close to the community whose building needs its supplies. Therefore, reclamation of quarries must be concerned with general neighborliness—avoidance of undue noise, visual assault, dust, and risk to the populace—as well as environmental control.

Final reclamation of the quarry is generally limited to providing for stable slopes. A common way to refer to these is as maximum natural stable slopes when saturated. This

refers to slopes that do not need the use of rock bolts, tensioned cables, or wire mesh to prevent rock falls or other slope failures. As an example, in Pennsylvania the height of each rock face is limited to a maximum of 15 m (50 ft) with a minimum 7.6-m (25-ft) bench. Careful mine scheduling will bring a large percentage of the quarry slopes into final configuration before exhaustion of the property. This minimizes unrecovered reclamation costs. A hypothetical example of mine scheduling to reduce final reclamation costs in quarrying follows:

Where water is to be impounded in the mined out quarry, the slope of the pit walls above the low water line should approximate the original contour or slope to a maximum of 35° measured from the horizontal. There should be a bench below the lowest water level that allows safe exit from the impoundment.

In addition to these requirements for the pit, visual barriers of mounded topsoil stored in the property line setback area or of permanently stored wastes should be used to restrict visibility of the pit from well-traveled areas. These mounds also reduce noise emanating from the quarry and its physical plant while the quarry is in operation. The mounds should be physically stable and planted with ground cover. Where there is sufficient space, and when the mounds are permanent, several rows of evergreen trees should be planted. The rows of trees should be staggered and mixed with a number of low-growing shrubs. To provide shielding in the winter and when the trees reach maturity, evergreens of a variety retaining limbs near the ground should be selected for the plantings.

STRIP MINING

The major difference between strip mining and open pits and quarries is that the strip mine tends to be developed promptly to its full depth and then progresses horizontally as the resource is recovered. Thus, in the progression of mining, considerable land surface is disturbed and large strip excavations result. These mined-out pits become ideal storage locations for the spoil being generated in the adjacent mining area. The characteristics have resulted in the current requirement that the mined-out pits be filled and returned to approximate original contour. Thus the reclamation process in strip mining is much more complex with several unit operations taking place simultaneously that directly impact on each other from a cost, operation, and planning standpoint. These unit operations are (1) backfilling, (2) leveling,

(3) development of stable outside spoil areas, (4) topsoil handling, and (5) seeding. A sixth, and continuing, operation is maintenance of reclaimed sites.

Backfilling.

In these bedded deposits, the newly removed overburden is placed as spoil in the adjacent mined-out area. This is the backfilling process. The more overburden that can be placed in the mined-out area, the smaller are the outside dumps and frequently the more cost effective the mining process.

In area strip mines, the percentage of total overburden that must be placed outside the mined area is usually small, sometimes 1% or less of the total overburden to be removed. The percentage that must be placed outside the mined area in mountaintop removal, in contrast, is substantial. Depending upon the steepness of the mountain slopes, the width of the mountain at the lowest seam, the number of seams mined, and the swell of the overburden, as much as 60% of the overburden must be placed outside of the mined areas, typically in valley fills (Cook and Kelly, 1976).

Current laws require that the mined-out areas of strip mining be returned to approximate original contour. However, there is a provision for modification of this requirement where a change in postmining land use is approved. In many such cases, this means larger outside dumps.

Where erosion control structures are to be used, they should be incorporated into the backfilling plan so that they can be constructed during the backfilling operation. These structures include erosion-control bench terraces and other structures such as down drains and reverse slopes.

In area strip mining, backfilling begins with the box cut being opened to the resource. Spoil from this cut must be placed on the surface or in another mined area to complete a fill. In the latter case, a permit must have been issued to allow the spoil to be placed there. Two methods of surface placement using dragline sidecasting are shown. In Fig. 1

Fig. 1. Plan and cross-sectional view of a box cut, end cut method (Bucyrus-Erie Co.).

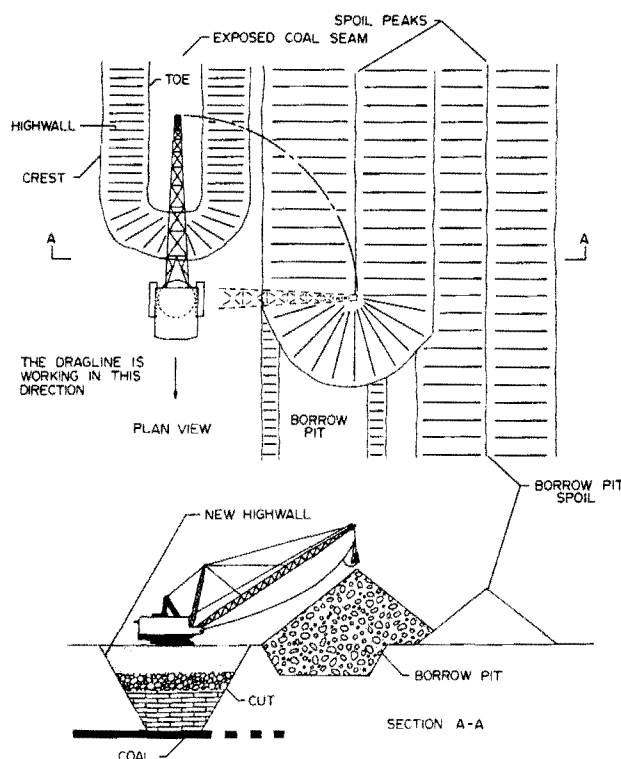

Fig. 2. Plan and cross-sectional view of a box cut being produced using the rehandle (borrow pit) method (Bucyrus-Erie Co.).

the overburden is not deep and can be placed directly on the surface. In Fig. 2, where the overburden is deep, the placement procedure is dictated by the type and size of equipment being used.

If a truck haulage system is being used to open the box cut, the spoil location becomes much more flexible. In such cases, consideration should be given to hauling the box cut overburden to a storage position next to the planned final cut. By such placement, it can be used to fill in the final cut and thus reduce or avoid a depression there while at the same time minimizing or avoiding having to reclaim outside box-cut spoil dumps.

The spoiling procedure for intermediate cuts is simply to cast the overburden in the mined-out area of the previous cut. The stacking ability of the spoil, the amount of spoil being placed in the mined-out cut, the space available in the mined-out cut, and the spoiling equipment used all are factors in the backfilled spoil profile. For dragline simple sidecasting, the mined-out spoil profile is determined using a range diagram such as shown in Fig. 3.

In contour mining, backfilling also takes place by continuously filling in the mined-out areas. The major concern in this type of strip mining is that filling in the mined zone to approximate original contour requires careful planning of spoil handling to allow sufficient material to be available for the final cuts. This aspect of contour mining is critical to the backfilling step if the best mining costs are to be achieved. Continuous backfilling is shown in Fig. 4. Intermittent backfilling, or block cut, is shown in Fig. 5.

In mountaintop removal mining, backfilling seldom achieves the approximate original contour. There are several reasons for this: (1) spoil slopes very seldom can be as steep

Fig. 3. A section of a range diagram for a large operation having rolling surface contours.

as the original slopes over the same vertical height, (2) the recovery of multiple seams requires outside placement of the spoil in valley fills, and (3) swell of spoil in the blasting and moving process gives more volume than can be safely placed in the mined-out space. Fig. 6 shows a typical mined-out configuration of a mountaintop removal mine. The difference in the height of the original surface and the surface after mining is the volume that was placed in the valley fill.

Leveling.

Once the backfilling process has been completed, leveling of the spoil piles begins. This unit operation generally utilizes dozers. In dragline cast spoil, it consists of pushing down the crests of spoil formed by the dragline, Fig. 7. The amount of effort required for this operation must be considered when the backfilling operation is planned. For example, a dragline cut may be developed such as to minimize the difference between spoil peaks and valleys. Fig. 8 illustrates this and how changes in the cut width, all other parameters remaining

the same, will materially affect the amount of material needed to be moved in the leveling operation.

In addition to cut width, another variable, the swing angle, needs to be optimized in dragline backfilling. Through variable, but planned, swing angles, the spoil peaks can be spread and reduced in height and thereby help to minimize the volume of spoil to be leveled.

Another piece of equipment having application in soil or soft rock overburden removal is the bucket wheel excavator. A closed or open connected machine can be used to advantage to level the peak/valley formation created by a dragline. The stacker for either type of machine can be positioned such that it fills in the valleys and thereby greatly reduces the effort required in the leveling unit operation. In addition, this machine may be used to keep soil and soft rock overburden on top of the zone being backfilled and leveled.

Finally a shovel/truck advance-bench operation stripping ahead of a dragline can also provide a very flexible spoiling operation. Selective placement of overburden can be

accomplished in an effective manner. If the truck spoiling procedure is designed in lifts, it keeps the stripped overburden stratigraphically on top in the backfilling sequence as well as minimizing the effort required for leveling. This and other tandem excavating schemes can be used effectively to achieve final reclamation.

Where environmentally possible, interburden and partings can also be removed with a truck/shovel operation and used to fill in valleys in the spoil. If a dragline is used to strip the interburden or partings, the spoiling procedure should provide for placing this material in the valleys, if from an operating or chemical standpoint this is possible and permissible.

Because the leveling operation can be substantial, special equipment has been developed. This equipment can be utilized where severe peak/valley formations are developed. The first of these is the V dozer blade. This blade is used with a 287-kW (385-hp) size dozer and is excellent for the first phase of leveling peaks. It is best suited for areas in

which a great deal of peak/valley spoil is generated each year. The blade is used to establish a flat running surface on the spoil peaks without backing the dozer. By moving down the spoil ridge, material is cast to each side. Leveling continues to the point where it has reached about the width of the blade. Then, the blade is disconnected because it is no longer effective. The V blade has been rated at 3823 to 7646 m³/hr (5,000 to 10,000 cu yd per hr) (Howland, 1975).

A second piece of equipment is the 14.6 m (48-ft) angle blade. The use of this blade is very effective for the bulk of the remainder of spoil leveling. It operates on the bench developed by the V blade and moves material by running parallel to the spoil crest and continuously cutting the spoil and allowing it to roll off into the valley. This blade has been rated at 4587 m³/hr (6000 cu yd per hr) and has been estimated to reduce spoil leveling costs by approximately 50% (Goris, 1980).

Final grading is begun once the leveling process has been completed. It is performed with motor graders or a grading bar attachment to a dozer (Goris, 1980). The main criterion here is that the surface thus created is not subject to excessive compaction by the grading equipment. Compaction will lead to an impermeable zone that retards the infiltration of percolating waters. By this retardation, topsoil can become saturated more rapidly, leading to vegetation survival rate reduction and difficulty of plant roots to penetrate as deeply as they should. On steep slopes, this compaction layer can also become a plane along which topsoil will slide when saturated.

The formation of the compacted layer can be reduced or eliminated by limiting the amount of travel by wheeled or high ground-pressure tracked vehicles as the final leveling is taking place. Wheeled vehicles place a high compactive effort into the ground. Two or more passes of wheeled equipment provide even greater compaction to the spoil (Phelps, et al., 1981). Track-mounted equipment also provide some compactive effort. Although they have a significantly lower ground pressure than wheeled equipment, their movement does provide a vibrating effect which produces some compaction. However, in many cases, tracked equipment provides the best vehicle, especially in steep slope regrading and leveling. If such a compacted layer has been formed, it should be broken up prior to spreading topsoil. This can be done

Fig. 7. Dozer grading of sidecast spoils (Cook and Kelly, 1976).

Fig. 8. Comparison of spoil bank spacing and height with wide and narrow pits (Mathematica, Inc., 1975)

through the use of disks, deep-chisel plows, or multishank rippers.

TOPSOILING

The topsoiling unit operation takes place after leveling. The operation places the growing medium for the plant cover over the rocky spoil in preparation for the final seeding phase. Topsoil is either brought from areas actively being cleared of soil in preparation for stripping or it is brought from topsoil stockpiles. The preferred method is to replace the topsoil directly on leveled backfill and not to stockpile. This procedure reduces rehandle and therefore the cost of topsoiling while at the same time minimizing the degradation of the soil as a plant medium.

Spreading topsoil on the regraded surface should be done in such a manner as not to recompact the surface upon which the topsoil is being placed. One method that can accomplish this is by dumping the soil from trucks and spreading with a dozer. In this manner, no tracking is done on the surface under the topsoil. Any compaction of the topsoil can be broken up by contour disking in preparation for planting. Another method for moving topsoil with a minimum of damage to the soil is to remove the entire profile with a front-end loader and tram it to its new location where it is replaced intact. This is akin to the establishment of lawns with turfs. Obviously, long tram distances would make this expensive. In small, or high-quality sites, this method bears consideration.

Where scrapers are used for relocating topsoil, care must be taken to minimize soil compaction (Holland and Phelps, 1986). This implies removal of the soil in as thick a lift as the machine can cut and replacement of the soil in a single lift of desired thickness. For example, one 305-mm (12-in.) lift would be preferred to two 152-mm (6-in.) lifts. Haul

routes should avoid, as much as possible, crossing soil zones and should be kept, on the removal side, on the subsoil and, on the replacement side, on the graded mine spoil.

SEEDING

Seeding is done with standard farm seeding machinery. This consists of operating chiseling-tillage equipment along contour to prepare the surface, broadcast seeding, and mulching. Mulching is used to provide adequate protection of the seedbed from erosion prior to the establishment of cover. At least 0.23 t (0.25 st) of mulch per 0.4 ha (acre) should be used, depending upon the level of sediment control desired. If the area is to go back into crops, straw mulch should be used, otherwise a hay mulch may be used.

Seeding can be done with a conventional broadcast seeder or, where steep slopes prevent this, hydroseeding. Hydroseeding is performed with a tank truck or tank trailer filled with a mixture of seed, fertilizer, water, and sometimes mulch (Fig. 9). The mixture is sprayed over the slopes using a monitor mounted on the truck or trailer. The tank is equipped with an agitator to prevent settling of the components of the mixture. When large areas require seeding, or conditions are wet, aerial application methods are very effective.

6.6.4 Mining and Reclamation Case Study

R. F. GOODRICH AND G. F. MCKEREGHAN

EDITOR'S INTRODUCTION

The following case study is included here because it gives insight into the complexity of mine planning for regions of well-developed land use. The state of Florida has enacted reclamation requirements, supplemented by county-enacted zoning ordinances, both of which require a high degree of planning before mining. We are grateful to IMC for sharing this interesting example.

RECLAMATION CASE STUDY: P-2 AREA

Land-Use Plans

The study area is located in Polk County, Florida, at IMC's Phosphoria phosphate mine and is designated P-2. The premining land uses were 20 ha (50 acres) of creek forest (Six-Mile Creek), 8 ha (20 acres) of citrus groves, 8 ha (20 acres) of railroad right-of-way, 72.8 ha (180 acres) of improved pasture, 145.7 ha (360 acres) of unimproved pasture, and 8 ha (20 acres) of power-line right-of-way and substation. The area covers about 283 ha (700 acres) of land in total.

Postmining land uses were planned to include 8 ha (20 acres) of railroad right-of-way, [4 ha (10 acres) relocated on reclaimed land], 39 ha (97 acres) of mine access corridors (dragline, power line, pipeline), 48 ha (118 acres) (three interconnected lakes) of water return and storage system, and 8 ha (20 acres) of power-line right-of-way/substation (never mined out). The mine access requirements were railroad/creek relocation (actual and potential) on the west, mine access (feed-line/power) on the north, and dragline/pipeline route on the east. The feed-line requirement on the north was justified by a reduction of 610 m (2000 ft) of pipe relocation from the Phosphoria washer to the Noralyn plant. Over the life of the Phosphoria washer, this would give a substantial reduction in power cost. Dragline access [61 m (200 ft)] on the east and north was required for IMC Noralyn mine draglines to move north and west to future mine areas. The entire P-2 area [283 ha (700 acres)] has been approved in accordance with state reclamation plans.

An important interim use of the P-2 area was for a settling area. About 180 ha (445 acres) of the mined-out area was being used, P-2 pond, for this purpose at the time the aerial photograph (Fig. 2) was taken. Pond size was determined by requirements set by the other area mines and limitations imposed by relocation requirements.

Mining and Processing

Strip mining was conducted with a walking electric dragline (Bucyrus-Erie 1250-B). Typical mining depth was 10.7 m (35 ft) with 5.5 m (18 ft) of sandy overburden and 5 m (17 ft) of matrix. Typically, the matrix consists of one-third phosphate ore, one-third silica sand (-16 to $+150$ mesh), and one-third clay/silt (-150 mesh).

The matrix is pumped by water slurry from the pit to the Phosphoria washer where the phosphate pebble ($-\frac{3}{4}$ in. $+11$ mesh) and feed (-1 mm to $+150$) are separated from the clay. Because Phosphoria has no beneficiation plant, the feed size particles are pumped to the Noralyn beneficiation plant about 5.6 km (3.5 miles) away. The clay size particles are disposed of in settling areas located in mined out areas with dams 6 to 12 m (20 to 40 ft) above grade. The bene-

ficiation plant recovers the phosphate concentrate (-16 to $+150$ mesh) from the silica sand by flotation. The tailings sand is then used as reclamation fill.

Reclamation

Reclamation fill was on-site cast overburden moved and recontoured with motor scrapers and bulldozers. Some overburden was pumped to the reclamation site from the mining dragline pit. In addition, some prestrip overburden was hauled to the reclamation zone to facilitate opening a new cut to avoid rehandling of overburden by the mining dragline. Two state road right-of-ways were mined against and immediately buttressed with shaped cast overburden. The three lakes were reclaimed to state and county standards. All reclaimed land areas were backfilled to approximate original contour. Premining coordination was accomplished between operations, reclamation waste disposal, and mine planning to identify zones requiring maximum overburden spoiling by the mining dragline to reduce earthmoving costs. Most of the remaining cast overburden in the area of the three lakes was removed with earthmoving equipment to build land areas, dams, and to maximize water storage volumes. The lakes were stocked with fish and will provide excellent recreational areas for Fin and Feather Club members.

Revegetation of the land areas was accomplished with 25 kg (55 lb) per acre of mixed seed consisting of 2.3 kg (5 lb) per acre of brown top millet (nurse crop), 15.9 kg (35 lb) per acre of Argentine bahia, and 6.8 kg (15 lb) per acre of Bermuda. Fertilizer application was 10N-10P-10K at 227 kg (500 lb) per acre. Mulch on slopes was 3.6 t (4 st) per acre of hay.

At this time the P-2 settling area is full and reclamation was started about $2\frac{1}{2}$ years ago. The reclamation of the P-2 settling area is to dewater the clays by draining excess water and rim-ditching the area, plus using low ground pressure flotation tractors to form a stable surface for pasture and tree planting. The clay surface will consolidate and lower from final clay deposition elevation about 3 m (10 ft) above original ground to a final reclamation surface at approximate original grade. The exterior dams will be resloped to no steeper than 1.2 m (4 ft) high to 0.3 m (1 ft) vertical. Although not planned, tailings could have been used from the Noralyn beneficiation plant to cap the P-2 settling area clays and improve the final reclamation surface beyond agricultural usage to possible light industrial use.

The Six-Mile Creek recirculating water system was tied (inflow) to the three lakes which are interconnected by culverts. Water decanted from the P-2 pond via spillways has the capability of entering the system on the north by direct inflow and on the south by routing it through the water return system and relocated Six-Mile Creek.

Costs

The total outside services cost for the P-2 area reclamation [103 ha (255 acres)] was \$1,409,000 or \$5526 per acre. Total earthmoving reclamation cost was \$1,343,000 and total contract services/supplies (culverts, spillway, grassing, mulching, and fertilizer) was \$66,000. The reclamation costs were incurred from 1977 through 1979. The P-2 settling area was constructed from 1978 through 1979 at a cost of \$1,929,000.

6.6.5 Topsoil Handling—A Biomass Productivity Approach

A.S. ROGOWSKI

B.E. WEINRICH

INTRODUCTION

The primary goal of any mining operation must remain the profitable recovery of a deposit, however, the need to reclaim land to previous or better use following mining cannot be overemphasized. Such reclamation constitutes a great challenge to ingenuity, because there may be an opportunity to create productive agricultural complexes where none existed before. Equally important is the preservation of existing agricultural land by restoring it to its original productivity. Novel approaches to reclamation have demonstrated that a mined area can be handsomely reclaimed, revegetated, and subsequently used for a variety of purposes, ranging from farming and ranching to recreation and wildlife habitat. Although initially the new "soil" will need to be supplemented with fertilizer and organic matter, eventually a full-fledged soil profile will form, perhaps not unlike the original profile it replaced.

The purpose of this section is to discuss different approaches to soil handling based on comparative biomass productivity criteria, subject to time and the existing climatic constraints. Although the reconstituted material is not immediately like the soil it replaces, it can be made into an adequate medium for plant growth through proper handling. With time, it should also develop its own particular layering (horizons) and characteristics. Consequently, the strict emphasis usually found in regulations on requirements for horizon and topsoil replacement is here modified to stress the need for a good rooting medium, and where applicable, to suggest possible measures to control excessive percolation, impeded drainage, and wind and water erosion potential.

An attempt is made to provide a broad overall framework of methodology for topsoil handling on a nationwide scale. It should be remembered, however, that this outline is no substitute for a detailed reclamation plan drawn with the help of the local Soil Conservation Service and University Extension specialists who are most knowledgeable about the details of soils, climate, and suitable vegetation in a particular area.

Scope and Extent

Although coal reserves constitute probably the largest areal deposits (Fig. 1) to be surface-mined, many other mineral resources produce large volumes of waste that are or will be in need of reclamation and revegetation. Some of the more important deposits are indicated in Fig. 1. Significant mining for uranium in Wyoming; copper in Utah, Arizona, and Montana; phosphate in Florida; and clay in Georgia result in areas that will need to be reclaimed in a manner similar to that now used by the coal industry. Examples of soil profiles from mining areas in many states will be used to illustrate potential problems and to describe an approach to topsoil management. The approach involves computation of a soil profile productivity index based on rather simple and readily available chemical and physical parameters. These parameters include soil properties such as pH, bulk density, texture, plant available water, aeration porosity, electrical conductivity, sodium adsorption ratio, and an estimate of root distribution. Computer values of the productivity

index for a reclaimed spoil profile are then modified by a biomass productivity potential of a given area, which is a function of mean annual temperature and precipitation at a particular site.

SOIL AND TOPSOIL

The productivity controlling zone in the reclamation operation is the topmost layer of the mined profile, which consists of a relatively thin upper crust of a regolith formed by weathering of the underlying rock mantle or sedimentary deposits. By examining the composition and behavior of this topmost layer over time, it may be possible to reconstitute the premined properties and structure of soils as closely as possible following reclamation. The soils that existed before mining started were formed during a long period and were subject to climatic, vegetative, topographic, and parent-material constraints. The challenge of present-day reclamation techniques is the ability to reconstruct the premined soil conditions, or, preferably to improve the soil or the landscape that existed prior to mining. In the humid East, concern with coal mine drainage tends to dominate much of the reclamation effort with less emphasis placed on surface conditions; however, great areas of the West could be made more suitable for plant growth by modifying present soil surface conditions.

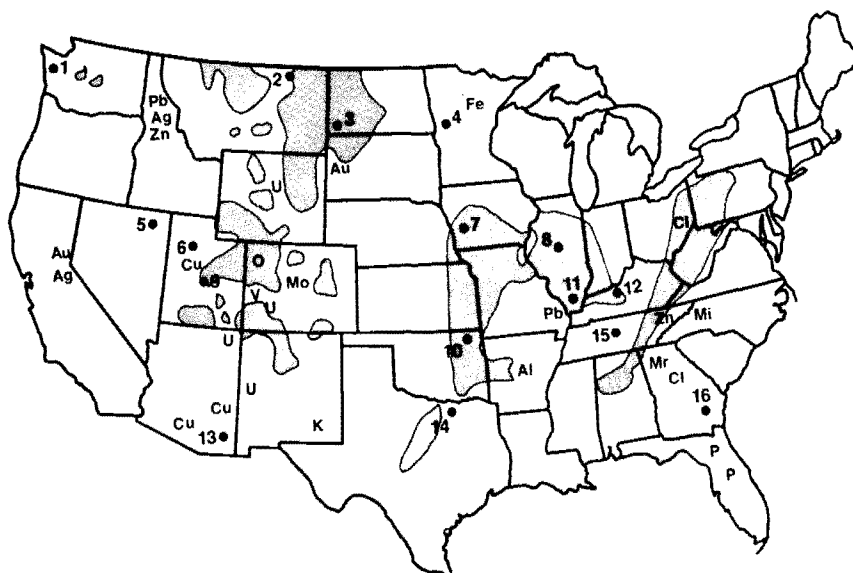

In the continental United States, soils have formed in response to varying climate, different parent materials, topography, and vegetative cover conditions. In some areas the nutrients have been leached out by abundant rainfall; in others, extensive decomposition of organic matter has created a nutrient-rich plant-growth medium. While some soils are far too dry to support much plant or animal life, others have developed impeding layers that obstruct water movement and root growth. Soil properties vary from field to field and from point to point. To consider topsoil handling in proper perspective, a brief review of background information is needed with particular emphasis on how these factors affect reconstructed profiles following reclamation.

Soil Properties

Definition of Soil: Soil can be defined as a system composed of partially or wholly weathered minerals; of animal, plant, and microbial residues in various stages of decay; and of living and metabolizing microbiota. This complex dynamic system in a loose state of aggregation also contains voids partially or completely filled with water, carbon dioxide, oxygen, and nitrogen and to a lesser extent with other gases. The mineral portion of the soil consists of unweathered rock fragments and weathered sands, silts, and clays. A vertical section through a soil showing different layers called *horizons* is known as a *soil profile*.

Soil Texture and Structure: Relative proportions of sand, silt, and clay (Fig. 2) determine the soil texture and have a significant effect on its chemical and physical properties. Mature soils have microscopic and macroscopic structure. The macroscopic structure, which can be seen with the naked eye, refers to the aggregation of primary particles into granular, blocky, platy, prismatic, or columnar clusters called *peds*. The micro-structure, which cannot be seen without the

Fig. 1. Distribution of coal reserves, shaded areas; of metals: Ag-silver, Au-gold, Cu-copper, Fe-iron, Mo-molybdenum, Pb-lead, V-vanadium, U-uranium, and Zn-zinc; of minerals: Cl-clay, K-potash, Mi-mica, Mr-marble, and P-phosphate; and of oilshale-O. Location of typical profiles: 1. Grays Harbor Co., WA; 2. Blaine Co., MT; 3. Bowman Co., ND; 4. Otter Trail Co., MN; 5. Elko Co., NV; 6. Salt Lake Co., UT; 7. Shelby Co., IA; 8. Logan Co., IL; 9. Sanpete Co., UT; 10. Ottawa Co., OK; 11. Johnson Co., IL; 12. Jefferson Co., KY; 13. Cochise Co., AZ; 14. Lamar Co., TX; 15. Williamson Co., TN; and 16. Brantley Co., GA.

aid of a microscope, is the structure of soil fabric. It may be thought of as a distribution in space of clay domains, humus domains, and microbial microhabitats among, and often binding together, the organic debris and mineral constituents. It depends on the mineralogical composition, profile microbial count, and species diversity, as well as organic matter content and particle size distribution. Young soils exhibit little structure either on the macro- or micro-scale and their profiles can be subdivided into weakly defined *A* and *C* horizons only. Mature soils usually have a better defined structure and their profiles can be differentiated readily into *A*, *B*, and *C* horizons. Mine soils, following reclamation, usually have no distinct natural horizons, and are not likely to show much structure for many years.

Fig. 2. Textural classification of soils.

Clay and Organic Matter: The topmost layer of soil usually contains the largest amounts of partially or fully decomposed organic matter called *humus*. Ordinarily, both the microbial population and humus decrease with depth and vary regionally. They are normally higher in the East and Midwest and lower in the dry West. In the continental United States they decrease from North to South because elevated temperatures lead to rapid decomposition of organic matter (National Research Council, 1981). The clay fraction, along with humus and microbiota, constitutes the active portion of soil fabric known as the *exchange complex*. The exchange complex is the primary seat of exchange reactions taking place in the soil and contributes to biochemical weathering of soil profile where soil clay minerals such as kaolinite, vermiculite, and montmorillonite are among some of the most important and interesting end products of the weathering cycle. Many Western soils having identifiable horizons are actually remnants of profiles that have developed under different climatic and vegetation regimes, whereas more recent Western soils developed in colluvium show little horizon differentiation.

The fertility level of Eastern and Midwestern topsoils is usually described by such properties as cation exchange capacity, base saturation, pH, total acidity, and carbon:nitrogen ratios (C:N). Fig. 3 shows a comparison of these properties between an original soil and some spoil materials in Pennsylvania. Western soils frequently contain more sodium, calcium, and magnesium salts in their exchange complex than their Eastern counterparts. If present in excess these can be damaging to plant growth. Measures such as electrical conductivity (*EC*) and sodium adsorption ratio (*SAR*) are generally used to describe the degree of the problem; the higher the *EC* and *SAR*, the bigger the problem.

Cation exchange capacity (CEC) in milliequivalents per 100 g (3.5 oz) of a soil is defined as a sum of exchangeable cations in a soil. It consists of calcium, magnesium, potassium, and sodium cations attached to the clay or organic matter constituents of the soil, plus such exchangeable hydrogen, aluminum, and traces of iron, manganese, and ammonium as may be present. The *CEC* generally reflects the soil humus content, pH, and the type and amount of clay

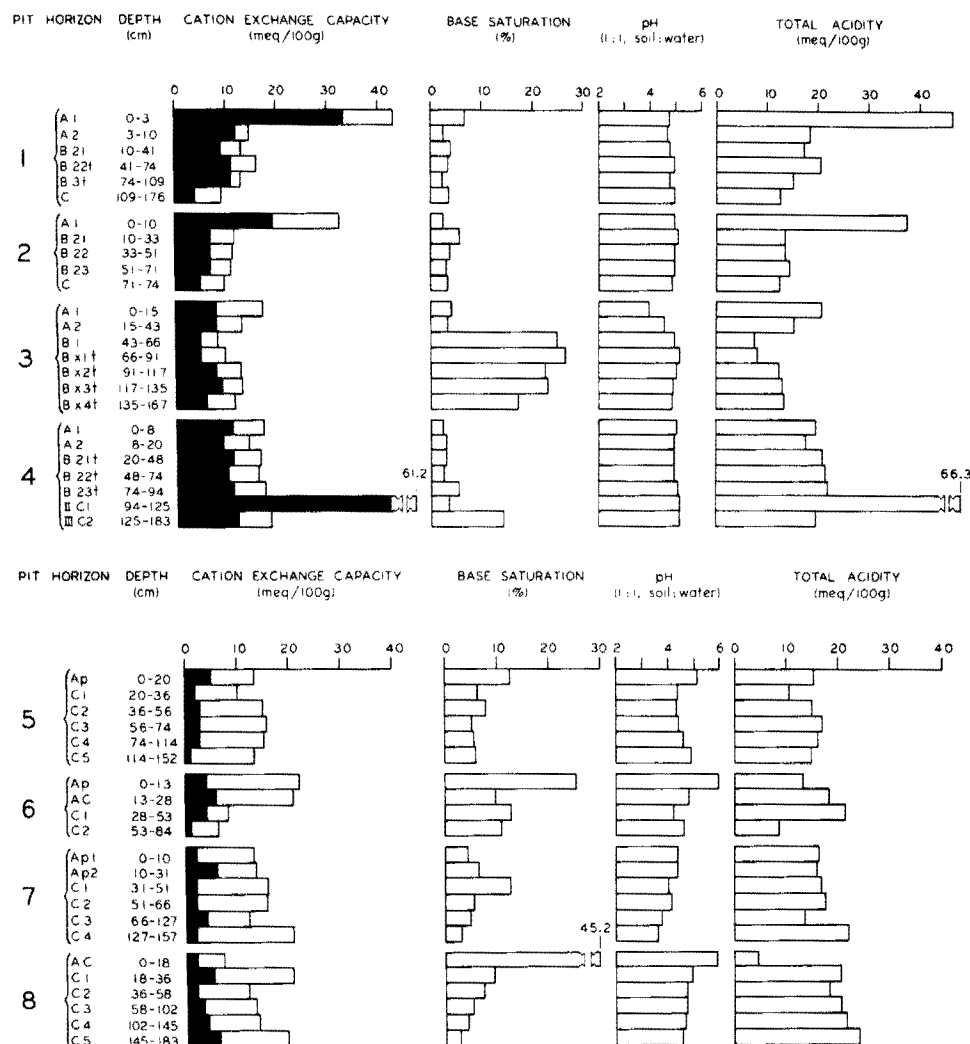

Fig. 3. Comparison of cation exchange capacity on the < 2 mm (0.08 in.) material and on the total volume of soil including coarse fragments (shaded), base saturation, pH, and total acidity in natural soils (1 to 4) and mine soils (5 to 6) in Pennsylvania (from Petersen, et al., 1978).

present. It varies with texture, ranging from 2- for sands to 60 meq/100 g for clays and clay loams. Variations within the same texture class often occur because of differences in organic matter content and pH level (Lyon, et al., 1952).

Base saturation (BS), usually defined as a fraction of CEC occupied by basic cations of calcium, magnesium, potassium and sodium describes how well the colloidal exchange complex of clay and humus is saturated with these cations. The difference, (CEC-BS), gives an estimate of *exchange acidity* of a given soil and represents acidity due to hydronium and aluminum ions. In soils of the humid regions there is usually a considerably higher level of exchange acidity and much lower pH values than in the soils of the arid regions. The *pH*, defined as the logarithm of the reciprocal of hydrogen ion concentration, reflects the concentration of hydrogen ions in soil solution. The resistance to change in pH for a given soil depends, however, on the amount of hydrogen and aluminum ions present on the exchange complex. When this is high, as in many Eastern soils, the soils are said to be highly *buffered* and may require much lime

to neutralize and make them suitable for plant growth. Consequently, horizons with low pH and high values of exchangeable acidity make poor candidates as topsoiling materials. In many Western soils the exchange complex is low in hydrogen but high in calcium, magnesium and sodium ions. As will be seen, this may lead to other problems.

When concentration of soluble salts of calcium and magnesium in soils increases because of water removal by evaporation or transpiration, excessive levels of salinity that will adversely affect plant growth may develop. The level of soil salinity is measured by the *electrical conductivity (EC)* of soil solution. Rhodes (1982) suggests that the only practical way to reduce excessive soluble salts in such soils is to leach them out of the root zone. Since many Western soils may contain such layers at the surface, it is particularly important not to use them for topsoiling during reclamation.

The second problem met with frequently in the West is posed by soils that contain excess sodium on their exchange complex. Such soils when leached with low-electrolyte concentration water, for example natural rain, lose their per-

meability (Reeve and Bower, 1960) by dispersion of clay and plugging of voids. A measure of sodium problem in these soils is the *sodium absorption ratio (SAR)*.

$$SAR = \frac{Na}{\sqrt{Ca + Mg/2}} \quad (1)$$

Soil as a Microecosystem: The system previously described is not a continuous one, but consists of a discrete distribution of chemically and organically active pockets (microhabitats) of clay and organic matter films along with a population of microbiota active in a soil solution. This loose assembly of microecosystems is linked together by a network of pores containing water, oxygen, and carbon dioxide continua that vary in response to climatic conditions, plant photosynthesis, and respiration demands as well as microbiological activity level. It has been established (Stotzky, 1974) that many factors will affect microbiological activity and productivity from point to point in the profile. Among these are the amount and kind of substrate material (humus), availability of mineral nutrients, ionic composition of soil solution, water content, temperature, atmospheric composition of soil air, pH, oxidation-reduction potentials, and particulate matter. Normal measures of microbial activity and productivity integrate local responses on a scale far larger than the scale of individual reactions. As a consequence the predictions regarding the microbial populations can only be made in a rather gross manner. For instance, it is known (Miller and Cameron, 1976) that as topsoil is stockpiled during mining, it loses much of the original microbiota. The reason for this may be the disruption of the more or less stable microhabitats, desiccation of soil solution, changes in the composition of soil air, elevation of temperature, too low or too high a pH, excess water or lack of it, as well as substrate wastage and decline (Stotzky, 1974). If the level of biological activity or the chemistry of soil solution changes, the fine clay particles may wash away from their original stable positions in the soil fabric and begin clogging the voids, creating anaerobic conditions and further affecting both the microbial population structure and numbers, provided of course the climatic conditions are such that microbial population can exist. Consequently, the response in a stockpiled soil is a complex one and specific causes for the loss of productivity are hard to define. Additions of organic matter and immediate placement of removed topsoil over a reclaimed spoil will minimize the effects of disruption.

Carbon-Nitrogen Ratio: It is in this context that the carbon-nitrogen ratio should be considered. In soil layers, such as those recommended for topsoiling, a close relationship exists between the organic matter and nitrogen contents. The ratio of carbon to nitrogen in the organic matter on the average is about 10 or 12:1 (Lyon, et al., 1952). The ratio varies regionally; it is lower in arid and warmer regions, higher in humid and cooler ones. For any one region, however, the ratio tends to stay about the same, provided the management of soils is comparable. In general, C:N ratio in plant residues is high (greater than 20:1), while in the soil microbiota it is on the order of 6:1. Thus, upon addition of organic residues to the soil there is an increase in soil decay organisms, accompanied by an evolution of carbon dioxide and a decrease in C:N ratio. In the process of humification, carbon is lost from the soil in a form of gas CO_2 , whereas nitrogen remains tied up in the microbial tissues. Eventually as the amount of available organic matter decreases, microbial activity slows down and some ammonia appears. With ensuing nitrification the product—nitrate nitrogen—is leached out of the profile by percolating water, and a quasi-

equilibrium condition prevails. The C:N ratio stays constant since now both carbon and nitrogen are being lost at the rate controlled by climate. The process has practical implications. If an organic matter source with a wide C:N ratio (such as oat straw) is added to a reclaimed topsoil, nitrate nitrogen level in the topsoil may substantially decrease until most of the straw is converted to humus. Thus, a growing or germinating cover crop is temporarily deprived of much nitrogen it needs. When adding organic matter to spoils, a high nitrogen source is preferred, since it depletes soil nitrogen least during decomposition and results in higher humus production. These concepts should be kept in mind when using mulches and or sewage sludge applications on disturbed land.

Soil Water: The movement of soil water within the voids is usually in response to profile concentration gradients and may be expressed as:

$$Q_N = C \nabla \phi \quad (2)$$

where Q_N is the water flow velocity vector, ϕ is the vector of total potential, C is a proportionality coefficient, and ∇ is an operator. To describe the change of soil water content (θ) with time (t), the following may be written,

$$\partial \theta / \partial t = \nabla \cdot (K \nabla \phi) \quad (3)$$

The proportionality coefficient, K , is then known as the soil *hydraulic conductivity* and

$$\phi = \psi + z + p \quad (4)$$

where ϕ , the total *soil water potential*, may be represented as a sum of *capillary potential* ψ , *gravitational potential* z , and at times other potentials, such as *osmotic potential* p . Values of the capillary potential (tensiometer pressure) as a function of water content are shown in Fig. 4a; the relationship is known as *soil moisture characteristic*. Quite often in mine soils the values of moisture characteristic have to be corrected for coarse fragment content with an accompanying decrease in water-holding capacity of the new soil. The amount of soil water held between the tensions of 33 and 1500 kPa is considered to be the *plant available water* and it is assumed that the water at tensions less than 33 kPa drains down to the water table under the influence of gravity. This is not strictly correct since in many soils water is often held in the root zone at tensions less than 33 kPa, and is available to some plants at tensions greater than 1500 kPa. Yet the notion of available water content provides a useful practical guide for field personnel.

Soil hydraulic conductivity values (K) vary as a function of soil water (Fig. 4b) and tensiometer pressure (Fig. 4c). A value of K at or near 0 tension is called a *saturated conductivity*. Fig. 4 shows examples of moisture characteristic and hydraulic conductivity for some Pennsylvania spoils. The plot of hydraulic conductivity values as a function of water content (Fig. 4b) suggests that for these spoil materials small changes in water content will result in large changes of hydraulic conductivity. This means that, even when spoil water content varies little, substantial changes in the flow rate can occur.

Soil Air: Plant roots and most microorganisms respire, using oxygen (O_2) and giving out carbon dioxide (CO_2). Gaseous and dissolved oxygen and carbon dioxide frequently have markedly heterogeneous distributions within a soil fabric. This can lead to the occurrence of simultaneous anaerobic and aerobic reactions in close proximity of each other within the profile. Zones that impede diffusion, dead end pores, or sites where CO_2 production is high (for example, zones where organic matter is actively converted to humus by decay or-

ganisms) often result in substantial differences in concentration over short distances. The oxygen-in-soil solution stimulates nitrification, while high concentrations of CO_2 ($> 50\%$) may be toxic to soil fungi. Free CO_2 is generally present in soil solutions below pH 6.3; above that, carbonates and bicarbonates predominate (Levy and Toutain, 1982). A well-aerated soil may contain 18 to 20.5% of O_2 on the average. This can drop to 10% after a rain and can be as low as 2% around respiring roots. In general, soil CO_2 level increases at the expense of O_2 ; usually its concentration will range between 0.3 and 3%. However, following incorporation of large amounts of organic matter, CO_2 levels may reach 10% or more. In most natural soils, O_2 concentration decreases rapidly with depth. Since mine soils often contain more coarse fragments and larger pores than natural soil, high oxygen concentrations can sometimes be observed at depth. Under these conditions and in pyrite-containing spoils, carbonate neutralization of the acid, which is produced by pyrite oxidation, is the dominant source of CO_2 . Levels of CO_2 as high as 18% have been recorded at 6 m (20 ft) in some Pennsylvania spoils (Jaynes, et al., 1983).

Soils and Land Use

This section will consider how the nature of soil itself may affect the manner in which it should be handled. Fig. 5 shows the areas where more than 50% of the land is in cropland (Fig. 5a) or rangeland (Fig. 5b), and Fig. 6 shows the location of major soil orders in relation to coal deposits in the continental United States. An order is a grouping of soils with similar taxonomic characteristics.

Appalachian coalfields are generally found on Inceptisols and Ultisols, those in the Midwest cropland are overlain by Alfisols and Mollisols, while on the Western range coal deposits underlie Entisols, Mollisols, and Aridisols. Table 1 shows the general properties of these soil orders primarily involved in surface mining for coal as well as other orders

that may be important in areas where mineral deposits other than coal are exploited. Brief descriptions follow (Jenny, 1980).

Inceptisols and Ultisols found in Appalachia are most amenable to change and manipulation. Since Inceptisols are young shallow soils and Ultisols have been extensively leached of nutrients, opportunity exists when reclaiming these areas to produce a better growth medium than the one they replace. The reclaimed area should be structured to absorb extensive percolation and to minimize erosion hazard. It should have, if possible, an organic matter high in nitrogen added to it, while being fertilized and limed extensively to provide sufficient nutrients for plant growth. Good plant growth and an oxidizing topsoil environment will in turn go a long way to minimize acid mine drainage on these areas.

A different situation exists in the Midwest. Here Mollisols and Alfisols are generally highly productive agricultural soils. This cropland has to be reclaimed so as to, at least, maintain soil productivity. Particular attention must be paid to preserving rich topsoil layers and restoring the physical properties, such as bulk density and aeration of original horizons.

In the West the overriding problem is lack of moisture. Some soils may be highly productive (Mollisols) and should be reclaimed accordingly, if supplemental irrigation is available. Other soils often exhibit high sodium content, or horizons in which clay, gypsum, or carbonates have accumulated (Aridisols). Under these conditions different horizons should be selected for use in order to minimize detrimental effects on vegetation and to maximize moisture usage.

Broadly speaking, Midwestern soils should be reclaimed as croplands, those in the West as rangelands, and Appalachian soils as woodlands. Thus, the original soil and climate will largely dictate the agronomic potential of the area and how best it should be handled. An example of a taxonomic soil description illustrates how much information about a

Fig. 5. Areas in the continental United States where more than 50% of the land is (a) in cropland and (b) in rangeland; insert gives principal coal deposits (Stewart, 1975).

given soil can be gained from its name alone (Soil Survey Staff, 1975). A profile in Grays Harbor County, Washington (No. 1 in Fig. 1), is classified as an Andic Dystrochrept. This soil belongs to an Inceptisol order. Thus, it is likely to be a relatively young soil, quite heterogeneous, with little clay translocation (Table 1). Since it is an Andic Dystrochrept, it is a moderately deep, freely drained, brownish or reddish soil commonly containing volcanic ash material (Soil Survey Staff, 1975, pp. 227, 228, 247, 249, 250). In a similar manner, taxonomic names of other soils not only describe the profile in reasonable detail, but also suggest where problems may arise.

Soil Variability

In attempting to predict a response of a soil, it should be remembered that soil properties are quite variable in space as well as in time. When general soil surveys are used for reclamation planning, it is well to recall (Beckett and Webster, 1971) that only about 50% of the sites chosen at random within a mapped soil series are likely to be occupied by profiles matching the definition of the profile for which the unit is named. Consequently, a large spatial variability is to be expected. Soils are dynamic: in time, moisture, temperature, and aeration statuses of a profile will change; materials will weather; topsoil will erode; plants will grow, die, and decay. The soil can never be adequately sampled to account for all the variability likely to be present in a soil profile. In general, Beckett and Webster (1971) concluded that soil variability increased with the size of the area sampled. Although Harradine (1949) found that young immature soils

showed more variability than developed mature profiles, young mine soils such as the ones discussed here may be less variable than soils from which they are derived. This, of course, should be the case when discrete soil layers become well mixed during handling, storage, and subsequent spreading during reclamation. If no overall mixing occurs, resulting mine soil would be quite variable over an area. This variability will be enhanced in time as spoils settle and erode and as plant cover changes.

CLIMATE AND SOIL MOISTURE REGIME

Some potential problems in topsoil handling that arise out of differences in soil moisture regimes will now be considered. These problems center primarily on shortage or excess of plant-available moisture, infiltration, runoff, water storage, and erosion. The status of soil moisture is only in part a function of climate. Many deep, permeable soils under high and evenly distributed rain have water available to plants most of the time. Even soils in arid climates are not necessarily dry. Their moisture status depends on their position in the landscape, since they can receive moisture from sources other than rain, such as deep seepage or snowmelt. However, since mining generally disturbs these features that have evolved over a considerable time period, moisture regimes of reconstructed profiles should be considered as being solely a result of climatic variables. The graphs in Figs. 7, 8, and 9 are based on average values of precipitation, temperature, and potential evapotranspiration (PE) and can provide a rather simple description of a profile's moisture regime. The area between the solid line (for example in Fig. 7),

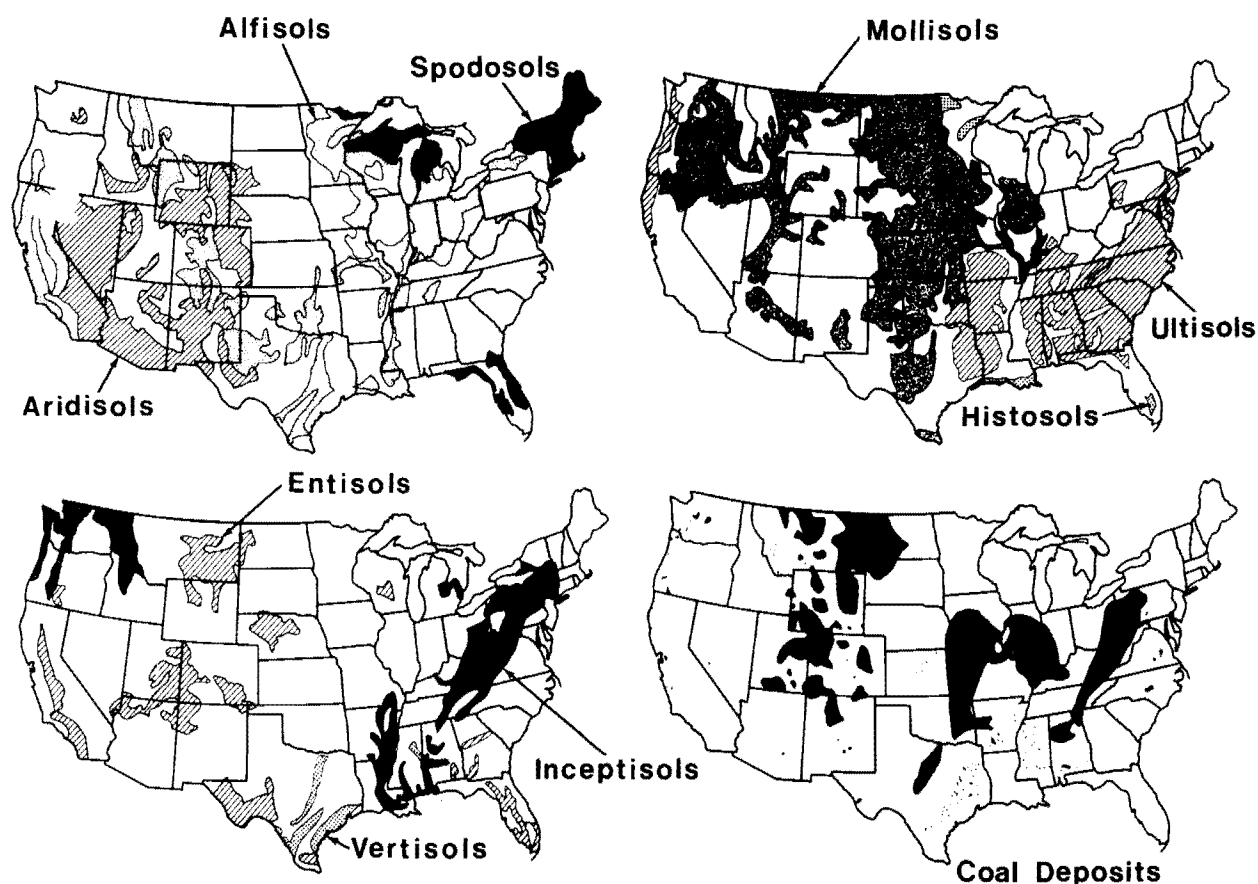

Fig. 6. Distribution of principal soil orders and coal deposits in the continental United States.

which joins all monthly precipitation normals, and the dashed line, which joins all PE normals, gives the status of soil moisture. Starting at the point where precipitation becomes greater than PE, the area to the right marked R (for recharge) shows the amount of water stored in the soil profile. Recharge usually begins sometime in the fall, extends to the extreme right of the diagram (early winter), and is continued on the extreme left (winter and summer). The amount of recharge is limited by the available water capacity (AWC) of the soil, in which case a vertical line is drawn when AWC becomes exhausted, and the area to the right of it is labeled S for surplus. Such surpluses may result in runoff, indicating a potential erosion problem in a given area. Recharge and surplus become limited when PE again exceeds precipitation. The area to the right, marked U (for utilization of water by plants), shows the amount of PE necessary to remove water held by soil at less than 1500 kPa tensions. When all the available water is removed from the profile, excess PE, labeled D, is the soil-moisture deficit before recharge begins. Constructing one of these diagrams for an appropriate soil is relatively easy if sufficient data are available. In particular, such a diagram should be made for a reconstructed mine soil profile to develop a meaningful revegetation plan. The data needed are soil available-water capacity, which for practical purposes may be taken as the amount of water held by the soil between 10 to 33 kPa and 1500 kPa*, monthly mean

temperature, and precipitation. Using appropriate tables and formulas, potential evapotranspiration (Thornthwaite, 1948) and soil moisture regime status can be calculated.

Computation of Soil Moisture Regime

The following illustrates a procedure for computing an estimated soil moisture budget, given profile water-holding capacity, and average monthly values of temperature and precipitation. Suppose that a site of interest is located in central Pennsylvania near the village of Pine Glen, 25 km (15.5 miles) northeast of the FAA weather station in Philipsburg. Normal monthly temperature and precipitation based on the 1941–1970 period and extracted from NOAA (1978) are given in lines 1 and 2 of Table 2.

Profile water-holding capacity down to 100-cm (39.4 in.) depth was estimated for Gilpin channery silt loam and Wharton silt loam as the sum of differences between water content, θ_0 , near saturation ($0.9 \theta_0$), and water content, θ_{15} , at 1500 kPa times layer thickness. Thus, potential water-holding capacity for Gilpin soil was found to be 291 mm (11.5 in.), and for Wharton soil it was found to be 230 mm (9 in.) in

servation Service office in different areas. Since they are usually given on a weight basis they need to be multiplied by bulk density to express them on the *per volume* basis. Soils-5 file, available at a nominal charge from Ames Statistical Laboratory, Ames, IA (c/o Harvey Terpstra), generally lists a range of available water for individual horizons of soils in inches/inch. These volumetric values are based on the difference between soil water held at 1500 and 33 kPa ($15\frac{1}{2}$ bar).

*For many soils these values are generally listed as $\frac{1}{100}$, $\frac{1}{10}$, and 15 bar in the County Soil Survey, or are available from the Soil Con-

Table 1. Properties of Soil Orders

Soil Order	Properties
Alfisols (aluminum and iron)	Soils that show shallow penetration of humus, much translocation of clay, medium high base saturation, and well-developed horizons.
Aridisols (dry)	Soils that lack plant available water for extended periods of time, have low humus, high base saturation, and may have excess sodium, carbonate, gypsum, and/or clay accumulation horizons.
Entisols (recent)	Young soils that are dominated by mineral soil material and show absence of distinct horizons.
Histosols (organic tissue)	Soils that have a high content of organic matter.
Inceptisols (beginning)	Relatively young heterogeneous soils that show little clay translocation, exhibit textures finer than loamy sand, variable chemical properties, and moderate (shallow) horizon development.
Mollisols (soft)	Soils with dark brown to black horizons rich in organic matter, and of soft consistence, may have high base saturation, and may have a zone of clay or calcium carbonate accumulation.
Oxisols (oxide)	Highly weathered soils generally found on old landscapes in tropics and subtropics that are rich in kaolinite, iron oxides, and often in humus.
Spodosols (wood ash)	In these soils a light gray or whitish horizon rests on a black or reddish horizon that is high in aluminum and may be high in iron.
Ultisols (last)	These soils show strong clay translocation, are intensely leached with low base saturation, and have generally low values of pH.
Vertisols	These are dark, high clay soils that exhibit deep cracks when dried out.

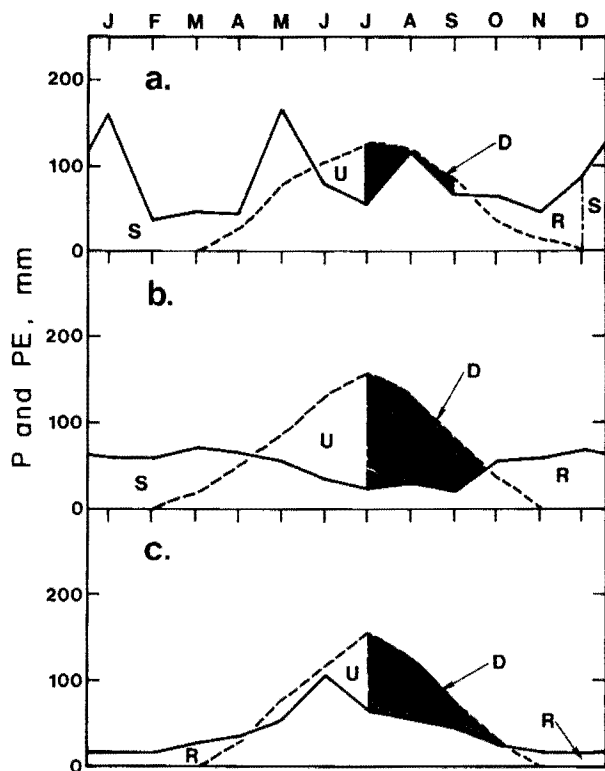

Fig. 7. Water budgets: (a) for Wharton soil, Centre Co., PA; (b) for a typical profile from Salt Lake Co., UT; and (c) for a typical profile from Bowman Co., ND; S = surplus, R = recharge, D = deficit, and U = utilization.

the top 100 cm (39.4 in.) of the profile. The monthly temperature and precipitation normals along with the profile water-holding capacity constitute the primary input into this moisture budgeting technique.

The first step is to compute potential evapotranspiration using Thornthwaite's (1948) method. The unadjusted (30 12-hr days) potential evapotranspiration (E) in millimeters is calculated as

$$E = 16(10 T/I)^a \quad (5)$$

where T is the mean monthly temperature in $^{\circ}\text{C}$, I is the annual heat index computed as the sum of monthly heat indices (i),

$$i = (T/5)^{1.514} \quad (6)$$

and a is an exponent approximated by

$$a = 0.000\ 000675I^3 - 0.0000771I^2 + 0.01792I + 0.49239 \quad (7)$$

Using Eqs. 5, 6, 7 and the monthly temperature data in Table 2, monthly heat indices i (Table 2, line 3) are computed and then the annual heat index $I = 36.48$ as a sum of monthly indices followed by exponent $a = 1.0763$ and unadjusted evapotranspiration E_u (Table 2, line 4). Values of unadjusted evapotranspiration E_u need to be adjusted for number of days in a month and approximate hours of sunlight. This is accomplished by extracting the appropriate correction factor from Table 3 (Table 2, line 5) and multiplying it by the unadjusted value of E_u . Table 3 was extracted from Table V of Thornthwaite (1948). For this example, a correction for latitude 41° is used.

Now water balance is computed for a reconstituted 100-cm (39.4-in.) profile at the site. Adjusted potential evapo-

Fig. 8. Primary climatic and moisture regimes of the United States: hot/dry climate, mediterranean climate, humid climate, and humid/dry climate; S = surplus, D = deficit, R = recharge, U = utilization; ° = temperature (Soil Survey Staff, 1975).

transpiration (PE) in millimeters (Table 2, line 6) is obtained by multiplying E_e in line 4 by correction in line 5 of Table 2. These values are then subtracted from monthly precipitation to provide the $P-PE$ index in line 7. At sites where precipitation exceeds potential evapotranspiration (annual value of $P-PE > 0$) the soil profiles likely will be near or at field capacity in the spring of the year, which is the case in Pennsylvania. Thus, water budgets for Gilpin, lines 8 and 10, and Wharton soils, lines 9 and 11 in Table 2, start with field capacity values in April. For subsequent months, values of ($P-PE$) in line 7 are subtracted from or added to the available water. If, as in lines 10 and 11, a water deficit develops, it is continued for as long as ($P-PE$) < 0. When ($P-PE$) in line 7 becomes positive, a new accumulation cycle begins (see values for October in lines 10 and 11 of Table 2). Fig. 7a graphically presents the water budget for Wharton

soil. The results show that under the assumption of 100 cm (39.4 in.) topsoiled profile, adequate moisture conditions for plant growth will prevail. However, should the operator reduce the thickness of topsoil to 30 cm (11.8 in.), moisture deficits (shaded area) can develop in July, August, and September. The water budgets in Table 2 are also predicated on normal values of precipitation. Should precipitation fall below normal, or should available water capacity of topsoiling materials be less than projected, moisture deficits can develop in other months also. It is worth noting that in January, February, and March excess precipitation may accumulate and be stored as snow, with potential for snowmelt, runoff, and erosion in early spring.

A somewhat different situation prevails when there is a slight overall annual moisture deficit, as for example, on a typical haploxerol soil (Table 4, Fig. 7b) in Salt Lake County,

† Available water capacity.

Utah. In the spring, on a reclaimed 100-cm (39.4-in.) profile of this soil, potential water-holding capacity would probably be satisfied; however, large water deficits could develop later on in the season and create a serious problem with revegetation.

A quite different situation prevails on a Typic Natriboroll soil in Bowman County, North Dakota (Table 5, Fig. 7c). Here only 39% of the available water-holding capacity is satisfied in the spring, resulting in much lower plant available water.

The three water budgets for Centre County, Pennsylvania, Salt Lake County, Utah, and Bowman County, North Dakota, illustrate the procedure used, the relative magnitudes and time of occurrence of moisture deficits (*D*), and likely field status of soil moisture in a reclaimed profile. Such a balance will have a direct bearing on how the topsoil for a given area needs to be handled, how much topsoil is needed, how reclamation should proceed, and what might be the best adapted plant species to use at the site. Of particular interest is the comparison of Fig. 7c with Figs. 7a and 7b. The profiles in Centre County, Pennsylvania, and Salt Lake County, Utah, appear to have surplus (*S*) moisture in the spring, possibly giving rise to some runoff and erosion but in general providing adequate moisture for most plant species. Although Fig. 7c does not show the moisture deficit (*D*) until some of the profile water has been utilized (*U*), the fact that the profile is actively recharging in the spring and that no surplus exists suggests that spring moisture conditions may at times be limiting.

Climatic Considerations

Fig. 8 shows the four primary soil climatic and moisture regimes encountered in the continental United States. A hot-dry climate is characterized by an extensive water deficit through most of the year. A humid climate regime is common to soils that have adequate well-distributed rainfall and generally suffer no water deficits. Extensive surpluses, however, may lead at times to considerable runoff and erosion. A humid/dry climate regime is somewhat less adequate than the humid regime in supplying plant needs because in the summer and early fall large water deficits can develop. Lastly, there is the Mediterranean type of climate characterized by recharge during winter months and hot-dry summers. These soil climatic regimes will now be considered for some of the areas where mining and reclamation prevail in the hope of gaining some prior insight into necessary and appropriate operations for handling the topsoil.

Fig. 9 shows some representative climatic data and soil moisture regimes for a cross section of sites in the continental United States (Soil Survey Staff, 1975) listed in Fig. 1. The climatic data and annual profile water budgets range from an abundant rainfall site in Grays Harbor County, Washington, typifying a very wet humid climate, to a desert site

in Cochise County, Arizona, with a hot and dry climate. Whereas an overabundance of soil moisture prevails at all times in the former, the latter is dry and lacks adequate moisture for most of the year. Thus, topsoil handling operations in western Washington may have to contend with wet soggy conditions, while such operations in Arizona would require supplemental irrigation to establish and maintain vegetation. The soils of Montana, North Dakota, Utah, and Nevada in Fig. 7 have a humid/dry type of climate and are likely to show profile moisture deficits of varying length and severity, suggesting that, although topsoil handling operations should be carried out during these times of deficit, the lack of adequate moisture may limit revegetation on these soils. Moisture regimes of soils from Minnesota, Iowa, Illinois, northeastern Oklahoma, eastern Texas, and Georgia exemplify a humid climate and adequate soil moisture conditions for plant growth. The danger here, however, is the large potential for erosion. Much of Appalachia (Tennessee and Kentucky data), although generally classified as humid, often displays an incipient humid/dry soil moisture regime, largely because of shallow, draughty soils. Although precipitation in Appalachia is usually quite adequate—and at times excessive enough to cause erosion—short periods of moisture deficits in the late summer and early fall are common. Finally, the moisture budget and climatic data from California typify a Mediterranean climate with rainy winters, hot dry summers, and substantial soil moisture deficits in summer and early fall. Topsoil handling is limited to summer periods, whereas reclamation and revegetation are dependent upon moisture reserves generated in winter and spring.

Local and Regional Implications

Fig. 10 shows some very general regional climatic attributes of the continental United States that ought to be kept in mind when considering soil handling procedures. The shaded area in Fig. 10a shows areas where potential contribution of cropland to watershed sediment yield is high, while Fig. 10b represents annual potential percolation in excess of 180 mm (7 in.) (Stewart, 1975, pp. 15, 26). Topsoil handling in these areas should incorporate safeguards against excessive erosion and should endeavor to provide sufficiently deep and pervious reconstituted profiles to accommodate percolation in excess of 180 mm (7 in.). Data in Figs. 10 a and b appear to exclude much of Appalachia. However, a very steep precipitation gradient and the variable, usually rather shallow, soil conditions make broad generalizations for Appalachia difficult if not impossible. If anything, the threat of severe erosion in Appalachia is often compounded by the constraint of limited profile storage. The challenge of topsoil handling in this area is not only to maximize profile storage in order to reduce potential erosion but also to minimize deep percolation that may contribute to acid mine drainage.

Mine reclamation and revegetation operations should

take into account not only the type of climate but also a projected spoil-profile water regime. The chances are that available water will be less, as much as 25 to 75% less (Pedersen, et al., 1980), in a reconstituted profile compared to natural soil. There are several reasons for this. In the East, large amounts of coarse fragments, mixed in with the spoil during reclamation, lower the water-holding capacity of the spoil, while in parts of the West high sodium and clay contents can substantially reduce infiltration and profile recharge during periods when moisture in the form of rain or snow is available. The amount and structure of topsoil material and the conditions at the soil-spoil interface can greatly affect both the total amount of water stored in the profile and water available for plant growth. In addition, compaction by heavy equipment can reduce aeration and increase amounts of water which, because it is held at higher tensions, is less available to plants. It should be remembered that natural soil profiles and layering result from long-time soil-forming processes that operate in response to climate, vegetation type, and relative amounts of available parent materials; on the other hand, man's knowledge of profile reconstruction is relatively new and short-lived.

ASSESSMENT OF PRODUCTIVITY POTENTIAL

A taxonomic soil description may contain much pertinent information about a soil, yet it says very little in a quantitative way of how productive a given soil is prior to mining and how productive it will be following mining. Consequently, it gives us little or no information on how the soil should be handled for optimum results.

Depending on whether the area mined is in the East, Midwest, West, or even South, it would be desirable to show objectively how mining affects soil productivity. It would also be desirable to propose two or more alternate ways of topsoil handling that attempt to minimize the impact of mining operations. To do this, we need to resort to modeling of soil productivity before and after a simulated mining operation.

Some currently available biomass productivity models approach the whole issue of productivity strictly from the perspective of climate. In Table 6, for example, biomass productivity (B) is calculated using mean annual values of temperature (Eq. 8) and precipitation (Eq. 9) in the so-called Miami model (Lieth, 1975, p. 246),

$$B_T = 3000 / (1 + \exp(1.315 - 0.119T)) \quad (8)$$

$$B_P = 3000 (1 - \exp(-0.000664P)) \quad (9)$$

$$\begin{aligned} B &= B_T, B_T \leq B_P \\ B &= B_P, B_P < B_T \end{aligned} \quad (10)$$

where B , B_T , and B_P are biomass productivity in ($\text{g}/\text{m}^2/\text{a}$), T is the mean annual temperature ($^{\circ}\text{C}$), and P is the mean annual precipitation (mm).

The site productivity is taken as the lesser of temperature (B_T) or precipitation (B_P) dependent values (these are the starred values in Table 6). The major drawbacks of the model are that it does not take soil into account and that it computes productivity on a rather gross scale. Other models approach the productivity potential through soil effects alone. Kiniry, et al. (1982), assumed that the productivity index was a

* Starred values are taken as site biomass productivity.

function of certain physical and chemical soil properties which are or may become limiting. The primary soil properties of interest were bulk density, aeration porosity, available water, pH, and electrical conductivity. The model was weighted with depth by root distribution. When climatic variables of temperature and precipitation were included in the computations, Kiniry, et al. (1982), findings showed a higher correlation between the calculated index and field measured yields than when they were not included.

The Kiniry, et al. (1982), approach has been modified by the authors here, and combined with Lieth's (1975) Miami model for assessment of site productivity potential before and after mining. This combined model will guide the user in handling his topsoil. It will allow the user to choose which soil horizons he wishes to save and what soil properties he needs to maintain, improve, or amend in the reconstituted spoil. Coupled with the soil-moisture budgeting procedure, the model can make a realistic appraisal of the site's reclamation potential. Because the values used in the computations of moisture budgets and productivity factors are in fact distributions in space and time, spanning a range of values with different probabilities of occurrence, this model should be used as a relative rather than as an absolute predictor of productivity. In this sense it is particularly suitable for use in mining operations where the user generally wants to know how pre- and postmining conditions relate to one another.

Productivity Index

Relative productivity of a site (*P*) in grams per meter squared per year (ounces per square foot per year) can be written,

$$P = B \sum_{i=1}^m W \prod_{j=1}^n x_j \quad (11)$$

where *B* is the biomass productivity, previously defined in Eq. 10; Σ is the summation operator over $i = 1, 2 \dots m$ horizons, or layers; *W* is the relative root distribution weighting function to 1 m (3.3 ft) depth, dimensionless; Π is the product operator; $x_1 \dots x_n$ are productivity factors, $n = 6$; $x_{j=1}$ is the available water, by volume; $x_{j=2}$ is the bulk

density, g/cm³; $x_{j=3}$ is the aeration porosity, by volume; $x_{j=4}$ is pH; $x_{j=5}$ is *EC*, ds/m; and $x_{j=6}$ is other, such as sodium absorption ratio, topography, or nitrogen content.

The undisturbed field soil profile usually consists of several distinct horizons in a solum of different depths. Similarly, plant root distributions vary. Some plants are shallow rooted, others have roots going down to considerable depths. However, in reconstituted topsoil, root distribution, at least initially, should be quite similar and reasonably constant for most profiles. The model is simplified by considering a 100-cm (39.4-in.) deep soil profile, assuming that such a profile approximates an average realistic depth of reclaimed topsoiled profile available for plant growth. It is furthermore assumed that below this 1 m (3.3 ft) of topsoil, there is an unconsolidated spoil material compacted at the surface and consisting of rock fragments or unweathered and mixed alluvial, lacustrine, or aeolian deposits with little or no potential to support plant life. For comparison purposes, the 100-cm (39.4-in.) depth is used throughout all examples, realizing that some topsoiled profiles may be shallower and others deeper than the value discussed here. Taylor and Terrell (1982) compiled information on rooting depth of over 200 plant species. Their data show that, on the average, 1.5 ± 1 m (5 ± 3 ft) is the depth reached by many roots or their branches, to which the absorption of water and nutrients takes place.

The structure of the model given in Eq. 11 is fairly simple. Productivity factors based on soil data are computed individually for each horizon by considering the minima, or at times the maxima, required for plant growth. These values are then multiplied together to show where the problems may arise. The products are subsequently multiplied by an appropriate weighting factor for each horizon, approximating plant root distribution, summed, and multiplied by a site biomass productivity potential (Table 6), giving an overall site productivity index. Details of the model operation are available in Rogowski and Weinrich (1982, 1987) and Rogowski (1985); computer code can be obtained by writing to the senior author.

The factors, x_j , which go into Eq. 11 are themselves a major source of soil productivity. They should be understood

both from the viewpoint of manipulating the model and reclaimed soil.

Weighting Factor (Roots): The roots distribution weighting factor, w , can be computed using the method proposed by Horn (1971) and adapted by Kiniry, et al. (1982). The principal assumption of this model is that the biomass production is a function of root growth that, in turn, depends primarily on available water, bulk density, pH, and where applicable, on conductivity, sodium adsorption ratio, and nutrient status of the soil. The weighting function is dependent upon total rooting depth, R , and the depth, r , of an individual layer in the soil profile. When integrated with depth and divided by total profile depletion, the method gives the root distribution weighting function (W) of Eq. 11 shown in Fig. 11. Others (Gardner, 1964) have described root distribution as decreasing logarithmically with depth.

Available Water Capacity: Available water capacity (AWC) in millimeters, $x_{1=15}$, should realistically describe the actual amount of water available for plant use during the growing season. This figure will vary depending on the climate, type of soil, and water use efficiency of a particular plant species. Table 7 shows available water capacity values (AWC) based on texture (Kiniry, et al., 1982; Peterson, et al., 1968). It has also been customary to express AWC as the difference between water contents of 33 and 1500 kPa.

Silty clay loam	0.145	145

* In 100 cm profile; for textures where $0.15 \leq \text{clay} \leq 0.40$ estimated water-holding capacity was computed as the average of textural limits for a given texture class from $\text{AWC} = 0.25-0.35 \text{ clay}$.

These values may be satisfactory for use in estimation, provided they reflect actual soil conditions during a growing season from planting to harvest. In the humid East, where the annual percolation is usually in excess of 180 mm (7 in.) (Fig. 10b), this generally is the case; however, further west, climatic consideration may override textural properties and the precipitation simply may not be enough to fill the available storage capacity. It is therefore suggested that AWC be chosen as the lesser of the values in Table 7 (or a value computed from a desorption curve at 33 and 1500 kPa) and the actual measured or estimated field values. While a limiting AWC value of 0.20 is probably satisfactory in the East and Midwest, a higher value may need to be used in the West where high evaporative demand and low rainfall lead to soils with pronounced summer moisture deficits. Under such conditions, model computations may also suggest to what extent supplemental irrigation is necessary on the newly reclaimed spoils.

Bulk Density and Aeration Porosity: Both soil bulk density and aeration porosity are modified during topsoil handling. Assuming that reserves of moisture and nutrients are adequate, soil productivity depends largely on how well plant roots can access these reserves. It has long been established that compacted layers impede root growth by preventing root elongation, limiting respiration, and at times contributing to water logging. Soil bulk density (BD), $x_{1=2}$, is commonly used as an index of compaction. Its effects, however, should be evaluated relative to soil texture, moisture, and moisture content at the time the soil is handled. Soil moisture content is particularly relevant to consider on reclaimed profiles where dense layers can often be produced if the topsoil is handled at or near so-called *optimum moisture content*. It is a well-known fact in soil mechanics that com-

Fig. 12. Productivity factor bulk density.

paction at the optimum moisture content will result in maximum attainable values of bulk density for a given soil layer (Terzaghi and Peck, 1948). Such values of bulk density and of the associated moisture content are usually listed in SCS County Soil Survey publications in the engineering properties tables. On the other hand, agriculturalists know that if a seedbed is not firm enough to be in good contact with a planted seed, poor germination and excessive droughtiness of a soil may result. To account for these limitations, a bulk density productivity factor (D) suggested by Kiniry, et al. (1982), Fig. 12, is used in the model. In general, BD suitable for plant growth will range from 1.30 to 1.80 g/cm³ (0.047 to 0.065 lb per cu in.). A good discussion of the effects of bulk density is given by Pearson (1965) and again by Bowen (1981).

In the productivity model, most physical and hydraulic effects of bulk density are assumed to be incorporated into the factor D . Other effects, such as adequate aeration of root growth medium so necessary for proper respiration and functioning of the roots, are grouped under the productivity factor aeration porosity. The two are related through the equation,

$$P_a = 1.0 - (BD/2.65) - \theta \quad (12)$$

where P_a , $x_{j=3}$, is the aeration porosity of a fully recharged profile, θ is the moisture content at field capacity, and 2.65 is the particle density of a mined soil. Field capacity will vary with soil texture, structure, and amount of organic matter present in the profile. In general, it should be somewhere between moisture contents measured at 10 and 33 kPa. Critical aeration porosity ($P_{crit} = 0.10$), when root growth may become restricted, ranges from 0.05 to 0.15 pore space by volume (Canell and Jackson, 1971; Pearson, 1965). Realistically aeration porosity effect should also include (but does not) a built-in dependence on time, a geometry factor to describe degree of continuity between air-filled pores and concentration level of CO₂. In some of the mine spoils where root respiration may compete for pore oxygen with oxidation of pyrite or iron in the profile, or when heavy additions of organic material (such as sludge) place an additional demand

on pore oxygen, it may well be advisable, particularly for deeper layers, to set P_{crit} higher than the recommended value. An operator should be concerned if at any time during the growing season, particularly when soil is wet, or following a heavy incorporation of organic matter, the soil oxygen concentration is likely to drop near critical level for even a short period of time (Canell and Jackson, 1981). In the event of water logging, for instance, aeration porosity may become quite critical.

At times, however, it may be desirable to minimize organic matter conversion or nutrient leaching in the topsoil that is stockpiled before being spread. Under these conditions, bulk density or aeration porosity may be manipulated so as to make the weighting factors for BD and P_a as small as possible.

pH: Soil reaction (pH), $x_{j=4}$, values appear particularly well suited to characterize the productivity response of re-constituted mine soil profiles in the East. Critical pH (Spurway, 1941) varies among soils and plant species and with time. The response to pH on acid soils may result from hydrogen, aluminum, and manganese toxicities and/or calcium or magnesium deficiencies. Thus, soils at the same value of pH could have limited yields for different reasons and the limiting factors would operate at different intensities in time and space (Adams, 1981; Pearson, 1965). Consequently, the model, which follows Neal's (1979) original formulation, should be used with caution and can be adjusted if sufficient information about a particular site or plant species is readily available. In the meantime, the model will provide sufficient guidance for the potential user in differentiating between the layers that may cause problems and those that will not.

The pH productivity factor (pH_p) is shown in Fig. 13, where pH denotes a measured value of pH in the 1:1 aqueous solution.

Electrical Conductivity (EC): An argument similar to that offered for pH applies as well to the effects of salinity on plant growth (Hoffman, 1981). Salinity effects may vary spatially with soil type, texture, and moisture status while different plant species will exhibit different tolerances. Salinity associated problems are almost certain to be present if reclamation is carried out in arid regions when original soils contain sufficient soluble salts derived either from marine

Fig. 13. Productivity factor pH.

deposits or from soil weathering. The problems can also arise in semiarid regions whenever rainfall is equal to evapotranspiration, as a result of upward artesian flow from aquifers, from overirrigation and from resulting saline seeps in adjacent areas, or if high water tables are present. Consequently, particular attention needs to be paid to the water regime and potential flow pathways in reconstituted profiles. Hoffman (1981) rates plants (his Table 9.3.1, p. 315) according to their salt tolerance, and suggests an appropriate form of the productivity factor, EC_F

$$EC_F = 1.0 - B(EC - A) \quad (13)$$

where A is salinity threshold value, B is the yield reduction per unit of salinity increase, and EC is the electrical conductivity of soil saturation extract in ds/m. Selected values abstracted from the Hoffman (1981) table are shown in Table 8. cursory inspection of Table 8 will show that EC_F can vary considerably depending on the crop used. Nevertheless, the model will alert the user that the salinity problem may exist if the profile is reclaimed in a similar form to original soil.

Sodium Saturation Ratio (SAR): Soils or soil horizons that have excess sodium on their exchange complex are known as sodic soils or sodic horizons. Such soils when leached with low electrolyte-content waters may show a marked decrease in permeability (Reeve and Bower, 1960; Frenkel, et al., 1978). Many studies (Rhoades, 1982) have dealt with reclamation of sodic soils and with evaluation of the irrigation water quality (Rhoades, 1972; Oster and Rhoades, 1976). Guidelines regarding the suitability of irrigation waters for agriculture, based on the type of predominant clay mineral, have been proposed (Ayers and Westcot, 1976) and questioned by more recent findings (Shainberg, et al., 1981; Frenkel, et al., 1978, and Suarez, et al., 1983). Currently the general consensus appears to be that the permeability of sodic soils depends on the electrolyte level a soil maintains—substantial decreases having been observed with low electrolyte contents (Shainberg, et al., 1981; Rhoades, 1982)—and may decrease with increasing pH (Suarez, et al., 1983). Such variations in permeability would have a significant effect on infiltration and subsequently on the amount of water available to plants for a given soil. Fig. 14 from Rhoades (1983) summarizes the present situation for some of the more sensitive arid land soils. On the average, Frenkel, et al. (1978) have observed an 83% reduction in permeability of montmorillonitic, kaolinitic, and vermiculitic soils when leached with distilled water as compared to 1N NaCl-CaCl solution.

Topography: This section has attempted to deal with the great complexity of a soil system in two dimensions by considering the distributions of the productivity index identified with a particular soil series. However, it is a well-known fact

Table 8. Salt Tolerance of Some Agricultural Crops

Crop	Threshold, A , ds/m	Yield reduction, B , per ds/m	Tolerance*

Fig. 14. Threshold values of adjusted sodium adsorption ratio of topsoil and electrical conductivity of infiltrating water (assumed to be in equilibrium with soil solution) for maintenance of soil permeability (from Rhoades, 1982).

in pedology (Jenny, 1980) that local relief, aspect, and drainage are among the most significant modifiers of the soil profile, particularly on a small scale. Thus, south-facing slopes may have a different vegetation, moisture, or temperature regime than north-facing ones. Soils developed on the hilltops are likely to be shallow compared to those developed near the base. Properties such as cation exchange capacity (CEC) or clay content may vary significantly with elevation (Fig. 15) and drainage and available moisture may range

Fig. 15. Distribution of clay and cation exchange capacity in a semiarid toposequence (from Nettleton, et al., 1968); Nos. 1, 2, 3, and 4 denote successive soil series that have developed at different elevations.

from excessive to impaired depending on position relative to the slope and degree of profile anisotropy (Zaslavsky and Rogowski, 1969).

Considerations such as these should be incorporated into the productivity assessment primarily through a representative sampling of the area to be reclaimed through use of parameter values that adequately reflect the area's heterogeneity. This is of paramount importance when attempting to reclaim land in Appalachia and elsewhere where mountainous or rapidly changing conditions prevail. Locally, climatic regimes, such as those in Fig. 8, normally separated by many hundreds of kilometers (miles), can appear within a span of a few hundred meters (feet) or exist separately on the windward or leeward sides of the same hill.

TYPICAL PROFILES

Fig. 1 shows the approximate location of counties that contain the typical profiles discussed here; Table 6 gives the values of biomass productivity index based on climate alone, and Appendix 1 lists the input and output values obtained following the execution of the Comparative Biomass Productivity Model.

Fig. 16 illustrates a typical computer program output sheet for a soil, in this case profile #3, a Mollisol, from Bowman County, North Dakota. The lower table in Fig. 16 contains input parameters such as bulk density, available water content, pH, and electrical conductivity as well as the mean annual temperature, precipitation, and clay content in each horizon. In computing available soil water-holding capacity, values higher than 0.20 cm/cm were set equal to 0.20. The actual water-holding capacity for this and other profiles listed in Appendix 1 was taken as the customary difference between water content at 33 and 1500 kPa. When

a profile is or can be fully recharged in the spring, the foregoing procedure may be correct. As mentioned previously, soils can and do retain water at tensions lower than 33 kPa ($\frac{1}{3}$ bar), and some plants can utilize water at tensions higher than 1500 kPa (15 bar). Thus, a good practical estimate of soil water-holding capacity is the difference between water held at 0.9 saturation and 1500 kPa (15 bar). In areas with insufficient rainfall, such as the Bowman County, North Dakota, example in Fig. 16, a more nearly correct estimate is to subtract, as was done in Table 9, water content at 1500 kPa from an estimated profile water content in the spring. As a last resort, when desorption data are lacking but values for clay content are available, water capacity can be estimated from clay content and climatic data, as discussed earlier (Table 7).

Productivity factor values given in the upper table of Fig. 16 for profile No. 3 constitute the output pertinent to choosing an appropriate procedure for topsoil handling. The magnitude of the five productivity factors is listed by depth and horizon for this soil in columns 6 through 10. The factors range from 0 (critical value exceeded) to 1 (no soil limitations to root growth). Their product in column 11 shows the quality of each layer. Thus in Fig. 16, the bottom layer [>97 cm (38 in.)], a 30 to 53-cm (12 to 21-in.) layer, and a 71 to 97-cm (28 to 38-in.) layer show low product values. In the bottom layer critical density is exceeded [1.84 g/cm^3 ($0.066 \text{ lb per cu in.}$)] while the 30 to 53-cm (12 to 21-in.) layer exhibits high density throughout. These layers, because of relatively higher clay contents, may compact too much during reclamation and should be handled with care. A more serious condition is that of the high electrical conductivity values that reduce the EC productivity factor in all layers below 30 cm (12 in.). The analysis suggests that at this site

97	100	0.24	0.20	0.09	0.45
Profile capacity, mm, 216		84			

- *1. Computed as water content at 0.33 kPa ($\frac{1}{3}$ bar) less water content at 1500 kPa (15 bar).
2. Values listed in Fig. 16.
3. Computed as the difference between the amount of water held by the profile following recharge in spring prior to planting and water content of 1500 kPa. (See Table 5 and Fig. 7c.) Subsequently all values under (1) were reduced in the ratio of actual to potential water-holding capacity $84/216 = 0.39$.
4. Column 3/column 2.

the 0 to 30-cm (0 to 12-in.) layer is best for plant growth; therefore it should be segregated and handled with care.

Column 12 in Fig. 16 gives the estimated profile root distribution, which when multiplied by the values in column 11 (product) and summed, gives the cumulative profile productivity index. The total profile productivity value of 0.6960 when multiplied by the biomass productivity (Table 6) gives the profile biomass productivity factor of 467 g/m²/a (1.53 oz per sq ft per year).

Because of limited recharge at this site (see Fig. 7c and Table 5), only part ($\frac{84}{216}$) of the available water capacity will be filled. Consequently, available water should be reduced by that amount (Table 9, column 3). The profile productivity will then be reduced in the ratio of column 3 to column 2 as given by column 4. When this correction is applied to

column 11 and subsequent steps are carried out as before, the profile biomass productivity drops to 236 g/m²/a (0.77 oz per sq ft per year).

The discussion of Fig. 16 illustrates the type of data the model will provide the user. With this kind of information, topsoil handling is guided so as to achieve optimum results, and individual results can be compared with results from other areas in the nation. Table 10 summarizes the output of the comparative biomass productivity model for some typical profiles. The input information for these profiles, chosen for soils from or near major mining areas, was extracted from a Soil Survey Staff (1975) publication, *Soil Taxonomy*. The inputs and outputs for all profiles are listed in Appendix 1. Here only selected ones will be discussed to illustrate a point.

Table 10. Biomass Productivity and Limitations for Selected Locations Near or in Mining Areas

No.	Location	Biomass, † g/m ² /a	Limitations*	Order†
1	Grays Harbor Co., Washington	1169	pH	I
2	Blaine Co., Montana	186	AW, BD, A, SAR	M
3	Bowman Co., North Dakota	464	AW, BD, A, EC, SAR	M
5	Elko Co., Nevada	224	AW, BD, A	M
6	Salt Lake Co., Utah	464	C	M
7	Shelby Co., Iowa	837	AW, BD, A	M
8	Logan Co., Illinois	1016	AW, BD, A	M
9	Sanpete Co., Utah	447	AW, C	M
10	Ottawa Co., Oklahoma	862	BD, A	A
11	Johnson Co., Illinois	1340	BD, A, pH	A
12	Jefferson Co., Kentucky	949	AW, BD, A, pH	A
13	Cochise Co., Arizona	51	AW, BD, A	AR
14	Collin Co., Texas	3	BD, SAR	V
15	Williamson Co., Tennessee	852	AW, BD, A, pH	A
17	Greenbrier Co., West Virginia	589	BD, pH	I

* Limitations: limiting factors, AW = available water, BD = bulk density, A = aeration, pH = pH, EC = electrical conductivity, C = Climate, SAR = sodium adsorption ratio.

† Soil order: I = inceptisol, M = mollisol, A = alfisol, AR = aridisol, V = vertisol.

‡ 1 g/m²/a \times 0.004467 = 1 ton per acre per year.

The biomass productivity values in Table 10 range from a low of 3 g/m²/a (0.0098 oz per sq ft per year) for a dense Vertisol in Texas (No. 14) and 51 g/m²/a (0.167 oz per sq ft per year) for a dry Aridisol in Arizona (No. 13) to highs of over 1000 g/m²/a (3.28 oz per sq ft per year) for an Inceptisol in Washington (No. 1) and a Mollisol in Illinois (No. 3), [these numbers translate to potential biomass production ranging from 1.4 kg (3 lb) to more than 13.4t/ha (6 tons per acre per year)]. Table 10 ranks these soils according to their productivity. Thus, most care should be taken in handling the really productive soil, like the profiles Nos. 1, 8, or 11, to restore them to nearly the same productivity values. Less productive soils, on the other hand, afford an opportunity for modifying the profile so as to increase productivity.

Profile No. 14, a Vertisol from Texas, has high sodium content, excessive bulk density throughout, and, associated with it, low aeration values in most horizons. If the area was managed properly so as to decrease the bulk density and increase aeration in the upper 56 cm (22 in.), this soil, despite adverse SAR, would have a potential biomass productivity in the neighborhood of 600 g/m²/a (1.97 oz per sq ft per year). Profile No. 13 (Arizona) lacks water, has high density, and low aeration values. Supplemental irrigation and proper management to decrease density and increase aeration could substantially increase productivity.

Even some of the better profiles can be improved. For instance, profile No. 1 from Washington, which is limited by pH, would benefit from liming. Profile No. 8 from Illinois, which is somewhat dry and in parts limited by bulk density and adequate aeration, could benefit from both an increase in water-holding capacity, perhaps by adding organic matter, and from an overall improvement in management, by decreasing density and increasing aeration. Here the user will have to make a choice. If the site is reclaimed as is, the projected profile productivity value would be 1016 g/m²/a (3.3 oz per sq ft per year). If the bulk density (BD) and aeration in the reconstituted profile were engineered so as to make their productivity factors equal to 1 (i.e., $BD \leq 1.30$), the biomass productivity value would increase to 1295 g/m²/a (4.24 oz per sq ft per year) for a productivity gain of about 27%. If on the other hand, water-holding capacity (AWC) was increased and other factors were kept constant, a somewhat lower increase to 1237 g/m²/a (4 oz per sq ft per year) (a 21% gain) would result. If both AWC and BD were improved, a biomass productivity increase to 1419 g/m²/a (4.65 oz per sq ft per year) (Table 6) could take place (a 40% gain). Under these circumstances, the profile would have no apparent limitations to plant growth and would be controlled by climate alone. A similar situation appears to exist in the two Utah profiles (Nos. 6 and 9) where climate plays the dominant role in determining the productivity potential. Under such circumstances reclamation to status quo and supplemental irrigation may be advised.

In much the same way, the other profiles listed can be analyzed. Their limitations to plant growth are expressed primarily in terms of available water (Nos. 2, 3, 5, 7, 8, 9, 12, 13, 15), bulk density and aeration (Nos. 2, 3, 5, 7, 8, 10, 11, 12, 13, 14, 16), pH (Nos. 1, 12, 15), EC (No. 3), SAR (Nos. 2, 3, 14), and climate (Nos. 6, 9). A different selection of soil profiles, with emphasis on Appalachia, would perhaps show a very strong influence of pH as, for example, in profile No. 17 (not shown in Fig. 1). Insufficient data other than climatic were found for profile Nos. 4 and 16; hence their biomass productivity values are not included.

RECOMMENDATIONS AND CONCLUSIONS

How best to handle topsoil on a mined area? The user should answer this question by first placing it in the context of the area's location. He will note that while abundant rain, erosion potential, and low pH values will create problems in the East, lack of water, salinity, excess sodium, and high bulk density will govern the use of reclamation techniques and topsoil handling in the West. The user should next examine the climate to see what kind of moisture budget he may expect in his area and simultaneously check the soils at the mine site for any possible problems that may arise because of their taxonomic classification. Having satisfied himself about the broad implications of location, climate, and soils, the user will need to get more specific. Execution of the comparative biomass model will point out the problem areas. Having identified his problem soils, the user may then want to select different options available, and to simulate possible outcomes, also by using the comparative biomass model. Having decided on the desired course of action, the user would want to consult with the soil conservation service or university extension personnel in this area to select specific techniques recommended to overcome particular problems on the area of interest.

It is hoped that the procedure outlined may streamline the solving of problems associated with topsoil handling, may identify areas that need closer attention, and may suggest techniques to improve productivity of a mined site compared to original soil.

6.6.6 Revegetation

RUSSELL J. HUTNIK
GUY W. MCKEE

INTRODUCTION

The benefits of a vegetative cover on land disturbed by mining are well known—erosion will be controlled, thereby lessening stream sedimentation; beauty will be restored to the landscape; and the land will become productive again.

As soon as the mining operation ceases, a natural process begins that, if left alone, eventually will culminate in a vegetative community in harmony with climatic and other environmental forces acting upon that particular site. This process, although inexorable, usually is too slow for today's society. And, the final community may not be the most desirable one. Emphasis therefore is placed on the rapid establishment of a vegetative cover composed of desirable species. Recently, laws have been passed to penalize operators who fail to achieve this goal.

Desirable species are those that can best achieve the goals of revegetation, as listed in the opening paragraph, both in the long-term as well as in the short-term. The vegetative cover, therefore, needs to be both rapidly achieved and persistent. As time goes on, the original community should develop into a natural community with little or no loss in its beneficial aspects at any time during this developmental period. Alternatively, the initial plant community can be managed so as to prevent natural succession, as in the case of agricultural land.

Natural communities usually are diverse. This diversity of species enables them to withstand disturbances caused by factors such as insects, diseases, and weather extremes. Diversity of plant species is highly desirable, even in the initial vegetation established on mined land.

ADVANCE PLANNING

Although all reclamation systems should be capable of achieving an immediate, permanent, and diverse vegetative cover, the operator, in developing a plan for a specific site, must consider three important points: (1) vegetation establishment is an integral part of the entire mining and reclamation operation; (2) methods will vary depending upon the objectives of revegetation and the plant species used; and (3) establishment methods will vary depending upon local differences in climate, geology, and soils.

The first point means that the operator should plan from the beginning how to achieve an adequate vegetative cover at a reasonable cost. In many cases, slight modification in the mining, grading, and resoiling operations can facilitate establishment of a vegetative cover. As far as possible, pyritic and other phytotoxic material should be kept out of the rooting zone. Compaction by heavy equipment should be kept to a minimum, and sharp differences in chemical or physical properties between the topsoil and underlying spoil layers should be avoided. Depending upon the plant species chosen and the method of seeding, some degree of surface irregularity can aid plant establishment. Examples are minor depressions from dozer cleats, disks and harrows, or cultipackers and similar tillage tools. If these goals are not accomplished before the revegetative phase, revegetation may be more expensive and less certain.

The second point means that the operator must have specific reclamation goals in mind. These could be restoration of vegetative conditions that existed prior to mining, development of a new and more productive plant community while maintaining the same land use, or development of a new land use pattern for the site. Usually, the operator will need to follow the dictates of laws and regulations currently governing mining and reclamation. Nevertheless, there is much to be gained by surpassing the minimum legal requirements; the operator will be better able to respond to future changes in the laws and regulations. In addition, the operator can reap the benefits of better public relations while improving the area disturbed by mining.

The third point means that environmental factors controlling plant establishment will vary from region to region and from site to site within a region. Adapted species and recommended practices will likewise vary between and within regions.

Consequently, there is no one "best" system of revegetation. Certain elements may be common for all sites but others will vary greatly from one site to another. This section will concentrate on the general aspects—those common to most revegetation systems. For systems applicable to a given region and land use, the reader should consult appropriate publications. Examples are "A Guide for Revegetating Coal Minesoils in the Eastern United States" (Vogel, 1981), a series of reports sponsored by the Fish and Wildlife Service, USDI (Rafaill and Vogel, 1978; Leedy, 1981; Nawrot, et al., 1982) and a series of user guides for mining and reclamation issued under the Surface Environment and Mining Program (SEAM) (USDA Forest Service, 1979a, 1979b, and 1982). Valuable information is contained in books such as *Reclamation of Drastically Disturbed Land* (Schaller and Sutton, 1978) and *The Restoration of Land* (Bradshaw and Chadwick, 1980). In addition, revegetation guides have been specifically developed for many states.

LIMITING SITE FACTORS

The selection of species and plant establishment techniques depends largely upon the nature of the site to be revegetated. An essential first step is to characterize the site, emphasizing those physical and chemical factors that are likely to limit or prevent plant establishment and growth. The reclamation specialist has a variety of options for revegetating sites with few, if any, limiting factors. But, where one or more factors seriously limit plant establishment, options may be greatly curtailed.

Much can be learned about the site to be revegetated by collecting data and samples during other phases of the mining operation. Especially important is the nature of the growing medium, both the topsoil (if it is to be replaced) and the subsoil. In properly planned operations, the spoil material best suited for plant growth should be placed near the surface, just beneath the surface topsoil layer. An analysis of drill cores and soil samples will help the operator identify overburden spoil materials and soil horizons best suited for plant growth. In some cases, the best spoil materials may be superior to the so-called "topsoil" as a medium for plant

growth. Topsoil generally is considered to be fertile and a good medium for plant growth. However, much of the topsoil on strip-mined sites is acidic, infertile, and low in capacity to hold and supply water and essential mineral elements. Topsoil, or rather surface soil, by virtue of its position at the surface may or may not be a good medium for plant growth and should be carefully analyzed prior to use.

Topsoil and subsoil samples should be collected from a number of locations on the site to be revegetated. Separate soil tests should be carried out for each 2 to 4-ha (5 to 10-acre) segment. The sample for each separate soil test should be composed of 10 to 20 subsamples. Most laboratories routinely test soil samples for pH; buffer pH; the concentration of important nutrient elements such as potassium, potash, calcium, and magnesium; conductivity or the concentration of certain soluble salts; and cation exchange capacity. Based upon such tests, recommendations are made for lime and fertilizer treatment. Although nitrogen usually is deficient on surface-mined land, there is no good rapid laboratory test for available nitrogen. Additional tests may be desirable in those areas where other soil properties may be limiting. Examples of such special tests are textural analysis, concentration of exchangeable aluminum and manganese (especially in Appalachian localities), concentration of sodium (especially in arid and semiarid regions of the west), and bulk density (especially in the midwest).

Additional observations, such as slope steepness, slope length, slope position, aspect, and color of the surface material, may reveal potential problems from high surface temperatures, water availability, and erosion potential.

SPECIES SELECTION

Availability

In most regions of the US, reclamation specialists can borrow freely from a large reservoir of research and experience in agronomy, horticulture, range science, and forestry. Species are selected based on their performance in previous plantings throughout the region. Species suitability, at times, can also be gleaned from studies of plant succession for the region involved. In general, early successional species should be best suited for revegetation projects. For such native or naturalized species, however, seed or other propagules may not be readily available in quantity. Also the native and naturalized successional species may not be capable of achieving a rapid cover. In fact, little is known about the reproductive habits and establishment of many native and naturalized plant species.

Adaptation

Since conditions on agricultural fields, even worn out and abandoned ones, may differ greatly from those on mined land, the suitability of various plant species for revegetating strip-mined sites must be based upon field research and upon a detailed knowledge of plant species. Even if a species performs well in field trials, the reclamation specialist is faced with a dilemma if seed is not readily available. Should he encourage the development of a seed enhancement program, which often is costly and time-consuming and for which there is no guarantee of success, or should he be content with less suitable species for which seed is in plentiful supply? In the latter case, the site may require extensive treatment with lime and fertilizer or other amendments.

Actually, a plant species often is much too broad a category for determining the suitability of plant materials for use on disturbed sites. Considerable adaptive differences have

been found among populations from different parts of a species range, i.e., ecotypes in the case of wild plants or cultivars in the case of cultivated plants. Ecotypic differentiation has been found to occur even in the same locality among plants growing on vastly different substrates. Thus, poor performance in field plantings may be due to a poor choice of ecotypes or cultivars rather than to a general lack of adaptation of the plant species. However, the range of adaptation within a given plant kind or plant species is limited. Thus, there may be statistically significant differences in aluminum tolerance between cultivars of birdsfoot trefoil (*Lotus corniculatus* L.), but the probability of finding a genotype of birdsfoot trefoil as tolerant to aluminum as that of sericea lespedeza [*Lespedeza cuneata* (Dum.) G. Don]] seems remote.

Species, ecotypes, and cultivars used for reclamation should be adapted to local biotic, climatic, and edaphic conditions. Problems sometimes develop with exotics, i.e., non-native perennial species or ecotypes, which grow well so long as weather conditions are near normal but which are eventually damaged when extreme weather conditions occur. Therefore, selections of plant species and cultivars should be based on long-term field trials and observations.

The number of species suitable for mine-land reclamation is far less than the number of climatically suited species, however; environmental factors other than climate can greatly limit the number of suitable plant species. This is especially true for so-called *orphan* banks—those which have been mined in the past and, for one reason or another, never satisfactorily revegetated.

Soil conditions on mined land often are such that the species selected must be able to tolerate extremes of surface temperatures, low or high levels of soil moisture, and a very low level of fertility. In the northeast, tolerance to high levels of acidity and exchangeable aluminum is also a desirable trait, as is tolerance to high levels of alkalinity and exchangeable sodium in semi-arid and arid regions of the west.

In addition to their differential ability to tolerate environmental extremes, plant species usually possess other traits that make them either more or less desirable for reclamation purposes. Among these are their susceptibility to insects and diseases, their potential to spread and become pests on sites adjacent to the mined land, their potential for wildlife food and cover, their ability to fix atmospheric nitrogen, their ability to spread vegetatively especially on actively eroding sites, their ability to withstand heavy recreational use, and their potential for producing valuable products such as Christmas trees and timber products.

Because of the desirability of achieving a diverse vegetative cover, plant species often must also be able to compete with and persist with other planted or wild species. Birdsfoot trefoil, for example, a species often used to revegetate strip-mined sites, is relatively intolerant of competition from associated grasses and weeds. Therefore, establishment practices and management should be selected to favor the birdsfoot trefoil. This means that the growth forms and habits of associated species must be compatible with the birdsfoot trefoil. If shorter growing species are mixed with taller species, the shorter species should possess a certain degree of shade tolerance. Warm-season species, i.e., those that make most of their growth in the summer, often are at a disadvantage when planted with cool-season species. A special problem is the difficulty of establishing woody plants in a dense herbaceous cover.

It often is highly desirable that the herbaceous species used be able to spread rapidly into bare areas, either through

vegetative means or through seed production and dissemination. Such characteristics also enable a species to maintain itself as individual plants die out. Some species that otherwise are suited, for example *Serecia lespedeza* in Pennsylvania, are not recommended because the growing season is so short that few seeds are produced in most years. Such problems are especially serious on strip mines at high elevations or at high latitudes.

Species tolerances and traits can be found in such publications as "Plant Materials for Use on Surface-Mined Lands in Arid and Semiarid Regions" (Thornburg, 1982), "Plant Performance on Surface Coal Mine Spoil in Eastern United States" (Ruffner, 1978), and descriptions of individual species published by the US Forest Service and the US Soil Conservation Service. Information can also be obtained from the Plant Materials Centers and Plant Materials Specialists of the US Soil Conservation Service and from plant scientists at agricultural experimental stations located in the various coal-mining states.

ESTABLISHMENT OF HERBACEOUS COVER

The key to successful revegetation of mined land is to ameliorate those factors that limit plant establishment and to create favorable conditions for seed germination and seedling growth.

Control of pH and Fertility

Chemical properties, such as pH and fertility, can be enhanced through liming and fertilizing. Rates should be based on laboratory analyses of soil samples. Proper control of pH is essential, since many plant nutrients are available only within a fairly narrow range centered around neutrality. Furthermore, toxic materials, such as aluminum and manganese, are present in soluble form only at pH values below 5.5 or above 8.0. Although lime can be applied in many forms, agricultural-grade ground limestone generally is recommended.

Fertilizers can be applied in many different forms. In the most commonly used fertilizers, the nutrients are readily available and some nutrients, particularly nitrogen and potassium, leach readily. Thus, increases in nutrient concentration may be short-lived, especially in coarse-textured soils with low cation exchange capacities. It is therefore important that a plant community be rapidly established; once established, the growing plants will conserve nutrients through recycling. On coarse-textured soils it may be desirable to topdress with additional fertilizer, especially nitrogen, in the second year or use a slow-release nitrogen fertilizer when seeding. The need for subsequent nitrogen fertilization can be minimized by including a legume or other nitrogen-fixing species, such as one of the alders (*Alnus* spp.), in the mixture. If supplies are available at competitive costs, waste products high in one or more essential nutrients can be substituted for all or part of conventional inorganic nutrients. These waste products include animal manure and treated municipal wastes such as sludge, garbage, and compost. Because the nutrients in such wastes are largely in organic form, they are released slowly. However, supplemental fertilization may be needed to compensate for use of nitrogen by the microorganisms decomposing the organic wastes. In the case of treated municipal wastes, care must be taken that heavy metal concentrations are within acceptable levels. Many states have laws and regulations governing the use of sewage sludge and similar wastes on land. Generally, the sludge must be analyzed before application and the site monitored after application of sludge.

The lime, fertilizer, and waste material should be incorporated deeply into the soil. Ideally, this can be achieved by liming and fertilizing the subsoil and tilling or disking. Following resspreading of the topsoil, the site is again limed, fertilized, and tilled or disked.

Adverse chemical problems associated with high levels of soluble salts or sodium are most difficult to correct. Leaching by excessive irrigation water is effective if the site is well drained. Chemical amendments also may be used. Two types of amendments are (1) soluble ammonium or calcium salts, such as ammonium sulfate, calcium chloride, or calcium sulfate (gypsum) applied individually or in combination; and (2) acids or acid formers such as sulfur, sulfuric acid, iron sulfate, or aluminum sulfate. Waste products, such as scrubber wastes from coal-burning power plants, may provide an economical source of calcium salts.

Seedbed

Physical problems related to soil texture are not easily overcome. If coal-burning electric generating stations are located nearby, the fly ash produced by the station often can be used to improve the physical and chemical conditions of the spoil or soil. The fly ash needs to be incorporated into the soil. The addition of organic matter, proper tillage, and the use of mulches can improve moisture relationships resulting from poor texture. Compaction is often a problem because of the use of heavy equipment in grading and re-soiling operations. Ripping and disking, or deep harrowing with a heavy cultivator or harrow, is recommended both before and after resspreading the topsoil. Moisture, aeration, and seedbed conditions will be improved and the often sharply contrasting interface between the spoil and the over-spread soil will be reduced.

Prior to seeding and planting, the seedbed should be prepared. Ideally, the surface should be relatively loose and friable with small cracks and crevices within which the seed can lodge. Thus, seeds will not be washed out during rainstorms, and water and fine sediment will tend to collect around the seed, thereby improving conditions for germination and seedling growth. As was previously mentioned, modern grading and re-soiling practices often tend to leave a smooth, hard-crust or compacted surface—a very unfavorable seedbed.

A favorable seedbed can be created by several methods. The simplest is to do the final grading and re-soiling with as little equipment use as possible, leaving the surface in a somewhat rough condition. A final pass by crawler tractor along the contour will create cleat tracks or depressions favorable to seed germination.

There are many types of harrows, disks, and chisel plows that can be used to scarify the surface; however, many sites are too rocky or too steep for use of conventional, lightweight farm equipment. Various types of rock-picker equipment are available but their use generally is of dubious economic value. If mine soils are extremely compacted, deep ripping may be required followed by disking or harrowing. The US Forest Service has an active project to develop equipment specifically for use in revegetation of strip mines and publishes annual reports entitled "Vegetative Rehabilitation and Equipment Workshop" (USDA Forest Service 1981, for example). If mine soils are extremely compacted, deep ripping may be required, followed by disking or harrowing.

In the arid and semi-arid regions of the west, and on rangelands, special equipment often is used to create a pitted or gouged surface. Snow and rain tend to collect in these

depressions, thereby improving the growing condition for plants.

Seeding Techniques

Seed can be either broadcast on the surface or drilled into the soil to the proper depth. The latter is preferred since broadcast seeds tend to be washed off the surface. Broadcast seeds also are subjected to extremes of moisture and temperature. However, seed drilling cannot be used on steep or excessively rocky land. Rangeland drills may be better suited for mine soil use than are drills developed for cropland use.

Broadcast seeding often is successful if a suitable seedbed exists and if the soil is cultipacked or otherwise treated after the seed is broadcast to cover the seed with a thin layer of soil. Aerial seeding can be used for mined land too rough or too inaccessible for ground equipment. However, unless mulched, seeding failures are common on such areas because adequate seedbed preparation seldom is done on these sites. When seed is broadcast, attempts to cover by dragging a tree or an old dozer track over the seeded area are poor techniques. Some seeds will be covered too deeply and others not deep enough. Use of a mulch after broadcast seeding is excellent and should be used when possible.

One system of broadcast seeding that is highly successful is hydroseeding. It can be used on steep rocky slopes, providing an access road exists. In this system, lime, fertilizer, seeds, and legume inoculant are mixed with water and applied as a slurry through high-pressure pumps and directional nozzles. All areas hydroseeded should be mulched.

Mulches

Regardless of the method of seeding, a mulch application is recommended. Mulches protect the surface against erosion and prevent desiccation and excessively high temperatures. Mulches can mean the difference between revegetation success and failure. They are especially valuable where the seeds have been broadcast and not subsequently covered with soil. Although a cellulose or similar type mulch can be incorporated into the hydroseeder slurry, it may prevent the seed from coming into contact with the mineral soil. Better results usually are obtained if the mulch is applied in a separate operation following hydroseeding.

The most commonly used mulches are grass hay and cereal straw. Straw mulch usually does not decay as rapidly as hay mulch but, on steep slopes, hay may do a better job of controlling erosion. Hay mulch may contain weed seeds, but this can be beneficial on mine soils where species diversity is desired. It has been suggested that hay and volunteer plants with their contained seeds be cut from old fields for use as mulch on mine soils to increase the proportion of native plants in the resulting vegetation.

The hay or straw should be applied uniformly to a depth of about 2 to 2.5 cm (0.75 to 1 in.); 5.5 to 7 t per ha (2.5 to 3 st per acre) of mulch should be sufficient. The mulching material should be "tacked" or otherwise held in place. Examples of tacking materials are asphalt emulsion, cellulose fiber, and certain chemicals. Mulch also can be anchored in place by pressing the hay or straw stems into the soil using a heavy disk with the blades set straight.

Other commonly used mulches are wood residues such as bark and wood chips. For most sites 85 to 115 m³ per ha (45 to 60 cu yd per acre) [1.0 to 1.3 cm ($\frac{1}{8}$ to $\frac{1}{2}$ in.) deep] should be sufficient. However, bark or wood chip mulch, because of the large fragment size, may limit the establishment of grasses and legumes. Cellulose fiber is commonly used in hydroseeding. However, as previously mentioned, mulching as a separate operation is the preferred method.

Materials, such as nets and netting, plastic film, and even crushed rock or pebbles, can be used as mulch or to hold mulches in place. They may be expensive but necessary on erosive sites.

Time of Seeding

Seeding usually is most successful if done in the early spring as soon as the soil is workable. At that time, moisture conditions are optimum. However, state and federal laws may require that a vegetative cover be established as soon after the final grading and resoiling as practical. This means that seeding may have to be done at any time during the growing season.

A rapid cover can be achieved with perennial grasses and legumes if seeded in the spring. However, it is often desirable to include annuals, especially small grains, in the mixture to achieve quick cover while the longer-lived and more persistent grass and legume species are becoming established. Spring oats (*Avena sativa* L.) can be seeded through the late summer. They usually winter-kill but the dead plants help protect the soil until the desired grasses and legumes resume growth the following spring. Species such as winter wheat (*Triticum aestivum* L.) or winter rye (*Secale cereale* L.) can be seeded in late summer and early fall, thereby providing soil protection over the winter.

At many locations, grasses and legumes can be planted along with a small grain, even during the late summer or early fall. The small grain provides quick cover for soil stabilization and the grasses and legumes provide long-term cover. However, in the central and northern United States, legume seedlings may require ten or more weeks of growing weather past germination to achieve sufficient growth and organic reserves to be winter hardy. Otherwise, they may winter-kill. For that reason, late plantings of legumes should contain a high percentage (35% or more) of "hard seed," i.e., seed with a coat impervious to water. Such hard seeds usually do not germinate the year seeded but do germinate the following year or years. Thus, hard seeds are an insurance against loss of all legume seedlings. In fact, many times the legume component on a strip-mined site came from hard seeds.

Legume Inoculation

Legumes should be inoculated with the appropriate species and strains of *Rhizobia*, the bacteria that induce the formation of nodules on the roots and fix atmospheric nitrogen into a form usable by plants. Since the root-nodule bacteria are sensitive to heat and drying, the legume seeds should not be inoculated until just before planting. Likewise, the inoculant should be kept out of the sun and kept cool. If the sites are particularly adverse, or if the seed is to be applied by a hydroseeder, apply inoculant liberally, up to five times the rate recommended on the legume packet.

Seed Quality and Seeding Rate

Seed should be high in quality, i.e., high in germination and purity. All states require that all seed sold be labeled for content of pure seed, inert matter, and weed seed as well as the germination percent and the date when the seed was tested. Seed for revegetation purposes should have been tested within the past five months.

In order to determine seeding rates, particularly with chaffy seed, one should first calculate pure live seed (PLS). This is the product of percentage pure seed and germination percentage divided by 100. The percentage PLS is then divided into the recommended pounds of seed and this value multiplied by 100. Thus, if the recommended seeding rate

for a certain grass is 9 kg/ha (8 lb per acre) and the purity is 96% with a germination of 90%, the adjusted planting rate would be 10.4 kg/ha (9.3 lb per acre). The calculations are as follows: $9 \text{ kg/ha} \times 96\% \div 90\% = 86.40 \text{ PLS}$ (96% \times 90% \div 100 = 86.40) = $0.104 \times 100 = 10.4 \text{ kg/ha}$.

Seed Mixes

There are two contrasting approaches with respect to formulating species mixtures. Some reclamation specialists prefer simple herbaceous mixtures, i.e., two to four species. A few specialists support complex mixtures of 6 to 12 or more plant species. In this latter case, the rationale is that there will be at least one species adapted to each microsite. However, complex mixtures often are very competitive, may be more difficult to seed, and the type of community established is less predictable. Often only a few species predominate, and some of the species in the mixture are so sparse that they have little influence on the nature of the community.

Species included in a mixture should be compatible rather than competitive during the establishment phase. Even with compatible species, one species seeded at an excessive rate can depress the establishment and growth of those species seeded with it. This is more likely to occur with small-seeded species, such as redtop (*Agrostis gigantea* Roth) or weeping lovegrass [(*Eragrostis curvula* (Schrader) Nees)], each of which has many seeds per kilogram. Redtop may have 10 million seeds per kilogram and weeping lovegrass 3 million. Seeding rates on especially adverse sites or on sites that are broadcast seeded should be increased by 50 to 100% over rates recommended for general use on less adverse sites.

ESTABLISHMENT OF TREES AND SHRUBS

Planting Materials

A number of different types of planting materials can be used. Seed of woody species can be included in the herbaceous seed mixture. This has been successful with species that have rapid early growth, such as black locust (*Robinia pseudo-acacia* L.). However, for many species the combination of slow growth during the first year and competition from grasses and legumes can result in seedlings too weak to survive the first winter. If a herbaceous cover is not part of the reclamation plan, pines can be successfully direct seeded, at least in the southern Appalachians. Seedlings of large seeded species, such as black walnut (*Juglans nigra* L.) and northern red oak (*Quercus rubra* L.) have been successfully established if the seed is buried and not destroyed by rodents.

Since there have been many failures with the direct seeding of woody plant species, most reclamation specialists prefer to plant seedlings. Seedlings are grown in tree nurseries for one or two years (sometimes longer), lifted, packaged in bundles, and shipped to the operator for planting in a bare-root condition. A recent development is the raising of seedlings in individual containers, usually in a greenhouse, and often for one year or less. The seedlings are then planted with the growing medium intact around the roots.

Studies comparing the two methods have shown mixed results. Apparently success is dependent more on quality of planting stock and care in planting than on the nature of the root at time of planting. Containerized seedlings do not require as much care during planting because the roots are not as likely to dry out. Also, the planting season can be extended later into the growing season with container-grown seedlings that have been kept refrigerated until the time of planting. Offsetting these advantages is the generally larger

size and more robust nature of the two-year-old bareroot stock raised in conventional nurseries compared to containerized seedlings.

A few woody species, particularly willows (*Salix* spp.) and hybrid poplars (*Populus* spp.), reproduce readily by stem cuttings. These can be planted on mine soils in either a rooted or unrooted form. Usually better results are obtained with unrooted cuttings; transplant shock often is a problem with rooted cuttings. However, environmental conditions, especially soil moisture levels, must remain favorable for several weeks following the planting of unrooted cuttings, until the roots are sufficiently developed. For this reason, it is usually difficult to establish unrooted cuttings in an existing herbaceous vegetation where shading and competition for water can affect establishment of the cutting.

Other types of plant materials have not been widely used but may have merit for certain species and under special conditions. Where nursery grown stock is difficult to obtain, as in interior Alaska, wildings (individual plants transplanted from the wild to another site) and plugs (clumps of vegetation, which may contain several plants) are dug and replanted to another site. An extension of the latter is to replace the entire organic mat that had been removed prior to mining or other disturbance. This practice may be useful in especially sensitive sites, such as Alaska tundra regions. For a few species, root and rhizome cuttings seem feasible, although for the most part, techniques have not been fully developed. An example is sweetfern [(*Comptonia peregrina* (L.) J. M. Coulter)].

In some cases no plant materials are added. The topsoil is limed, fertilized, and respread on the site. Vegetation develops from seed and root or rhizome fragments already in the topsoil and from seed blown into the area. This practice is especially appropriate if the goal is the restoration of the site to the former condition. However, it usually is not appropriate if a rapid cover is needed for erosion control or is mandated by law. Seed hay mulch also has been used. Seeds in the mulch are sufficient in some cases to establish a cover.

Quality of Planting Stock

Seedlings should have a good balance between root and top development and should have a high degree of robustness. The latter is best measured by the diameter of the stem at ground level, the larger the diameter, the more robust the seedling. However, seedlings beyond a certain size are difficult to plant and survival often drops because of improper planting. Recommended minimum and maximum diameters at the root collar vary with species, but often are given as 0.4 cm (0.15 in.) and 0.9 cm (0.35 in.), respectively.

Roots of older plants often are pruned to a length of 15 to 20 cm (6 to 8 in.) to facilitate planting. Tops of hardwood seedlings should also be pruned to achieve a good balance between the top and root systems. Top pruning is not recommended for conifer seedlings. Seedlings should have a healthy, vigorous appearance. Seedlings with poorly developed root systems and conifer seedlings with sparse or yellowish foliage should be discarded.

The quality of tree and shrub seedlings could be enhanced in many cases if they were inoculated with the proper mycorrhizal fungi, thereby leading to more efficient nutrient uptake. Considerable progress has been made in this area, and it seems likely that such inoculated seedlings will be commercially available in the near future. Many nursery-grown seedlings are naturally inoculated in the seedbed, although the fungi species present may not be the best suited for conditions prevailing on the mined sites.

Hybrid poplar cuttings should be 20 to 30 cm (8 to 12 in.) in length and 1 to 2 cm ($\frac{3}{8}$ to $\frac{1}{2}$ in.) in diameter. They should be taken from stems or branches of trees during the dormant season. Survival may be poor if the cuttings are taken just before the buds begin to expand.

Care of Planting Stock

Upon receipt, the unopened bundles of seedlings should be moistened and stored in a cool, shaded place. If they cannot be planted within a few days, they should either be placed in cold storage or "heeled in." Heeling in consists of digging a trench in the soil in a moist shady location, breaking the bundles, and spreading the seedlings out evenly, filling in with soil and watering.

Care should be taken that the roots do not dry out either before or during planting. During planting, seedlings should be carried either in a canvas planting bag or bucket with moist peat in the bottom, or in a bucket with sufficient water to cover the roots. Root drying during planting can be retarded by dipping the roots in a kaolin clay slurry or in gel-like substances that are commercially available.

Time of Planting

Unlike establishing a herbaceous cover where planting can be done almost any time if care is used, planting of tree and shrub seedlings is best limited to the spring and, in some cases, the fall. Soil moisture, temperature, and light conditions are most favorable in the spring. Seedling survival is poor if the seedlings are planted after the initiation of growth. Containerized seedlings are an exception, but generally, even these have a lower survival when planted in the summer as compared to early spring.

Fall planting is recommended only in regions with mild winters. Otherwise, root growth is not sufficient to carry the seedling through the winter. Fall-planted seedlings are more susceptible to frost heaving than spring-planted ones.

Species Mixtures

As suggested for herbaceous cover, a mixture of woody species rather than a single one should be planted on any one site. Such mixtures provide a greater range of adaptation to the variation in microclimates and soils that often exists in close proximity on disturbed areas. Species mixtures can provide a variety of benefits in the form of site protection and wildlife food and habitat, and maintain these benefits more fully from one season to another and from year to year than a monoculture. There is also less likelihood that a diverse plant cover will be destroyed by environmental stresses such as drought, diseases, and insects. If hybrid poplars are selected for planting, a number of different clones should be used.

Tree and shrub mixtures can be planted by small blocks of each species, by strips (several rows of the same species), by individual rows, or by individual plants. Mixtures of species by small blocks are relatively easy to make and chances for success are usually better than for other types of mixtures. Mixtures by individual plants are not only difficult to design and carry out, but the seedlings are subject to interspecific competition. If one species is less competitive than the others in a mixture, the seedlings of that species tend to be suppressed or even eliminated from the stand.

Nevertheless, there are distinct benefits from mixtures by individual plants or individual rows. Inclusion of a nitrogen-fixing plant species in the mixture, either as individual plants or as individual rows, often will increase the growth of the associated species. This may not happen if the nitrogen-fixing species has rapid juvenile growth, and the associated species

are slower growing and relatively shade intolerant. It is, therefore, important that the reclamation specialist take into account the growth habits and the relative tolerance of the various species when mixtures by individual plants or rows are planned.

Planting mixtures in strips is especially appropriate if the planned postmining land use is for wildlife purposes. A series of strips of species differing in growth habit will result in a large "edge" effect. Furthermore, all necessary habitat elements, i.e., food, escape cover, and reproductive cover, for a wildlife species can be found within a relatively small area.

Spacing

Tree seedlings should be spaced far enough apart so that merchantable products can be obtained in the first thinning, but close enough together so that the trees will develop a good form. Hardwood species, except hybrid poplars, should be at somewhat closer spacings than the conifers. Recommended spacings are 1.8×2.0 m (6×7 ft) or 2×2 m (7×7 ft) for hardwoods, 2.5×2.5 m (8×8 ft) for hybrid poplars [(or 2×2 m (7×7 ft) if planted in alternate rows with other species)], and 2.0×2.5 m (7×8 ft) or 2.5×2.5 m (8×8 ft) for conifers. Closer spacings [1.8×1.8 m (6×6 ft)] may be desirable for wildlife plantings, for critical sites such as steep slopes, or for adverse sites where substantial mortality may occur. Even closer spacing [1.5×1.5 m (5×5 ft)] is recommended for Christmas tree plantations. Shrubs, depending upon the species, may require closer spacings.

Planting Methods

The seedlings can be hand planted, or, if the area is not too rocky or steep, machine planted. The two most commonly used hand-planting tools are the dibble, or planting bar, and the mattock. These can create holes 15 to 20 cm (6 to 8 in.) or more in depth. Because the dibble is forced down with the foot, it may be a better choice on rocky or compacted mine soils than the mattock.

It is imperative that the roots of seedlings be placed properly within the hole. The seedlings should be planted to the same depth as they had been growing in the nursery bed. The roots should be well distributed within the hole. Roots that are restricted or bent (J shaped) should be avoided. Such trees seldom develop properly, and after several years usually die.

After the soil is replaced around the roots of the seedling, it should be tamped in with the foot. If air spaces are left around the roots, the roots may dry and die; even if the roots don't die, water and nutrient uptake may be impeded.

Container-grown seedlings have similar requirements as to proper planting depth and firming the soil around the root plug. Care should be taken to keep the root plug intact when removing the seedling from the container and placing it in the hole.

Unrooted cuttings can also be planted with a dibble or mattock, but preferably with a planting bar made from a sharpened steel rod about 2 cm ($\frac{3}{4}$ in.) in diameter. They should be planted so that only about 5 cm (2 in.) of the cutting is above the ground level, the uppermost bud should be about 2.5 cm (1 in.) above the ground level. This will make it more likely that the base of the cutting is in contact with moist soil, that a single stem will develop rather than multiple shoots, and that the tender, developing shoot does not make contact with the hot surface of the mine soil. As with seedlings, the soil should be packed closely around the cuttings so that there is good contact with the soil.

Tractor-drawn tree planting machines are able to plant

seedlings at a rapid rate. However, the terrain must be suitable. They cannot be readily used on sites that have been gouged or pitted to collect precipitation. Planting machines should be operated on the contour since most machines leave a small furrow that can serve to channel runoff and eventually lead to gullies. It is desirable to firm the soil around the seedlings following planting.

WOODY-HERBACEOUS COMBINATIONS

Many tree and shrub species exhibit poor growth during the first year following planting. Because of this "transplanting shock," they are not highly competitive. Survival often will be low if they are planted in an already established dense herbaceous cover. Ironically, the better the job an operator does in achieving short-term site protection, the poorer are his chances to obtain long-term objectives. Tree or shrub survival and growth may be reduced, even when the herbaceous cover is less than complete or where woody seedlings are planted at the same time that the seed is sown.

Several steps can be taken to reduce this problem. As previously mentioned, woody species can be used that are especially competitive even during the first year following planting. However, this option will limit the tree or shrub species available for use by the operator. A second method, if permitted by reclamation laws and regulations, is to leave bare, i.e., unseeded strips, about 0.6 m (2 ft) in width on the contour. Woody plant seedlings are planted in the bare strip. This will permit the woody plant seedlings to become established during the year or two required for the herbaceous vegetation to spread into the unseeded area. Another possibility is to reduce the fertilization and/or herbaceous seeding rates so as to achieve a less dense, and hence less competitive, herbaceous cover. However, there is a risk that cover so obtained will not meet legal requirements or achieve the objectives of short-term site protection.

If possible, the tree or shrub seedlings should be planted at the time of seed sowing. However, this is not always possible. If planting must be done in a dense cover, some form of competition control is necessary. Herbiciding a strip about 0.6 m (2 ft) wide into which the seedlings are planted or herbiciding a spot around each seedling are promising methods. Mechanical control, either by plowing strips or by scalping around the seedlings, often is less successful because regrowth of forbs, grasses, and legumes into the denuded areas can be rapid.

POST-PLANTING OPERATIONS

Although desiccation is one of the major causes of revegetation failure on surface mines, irrigation is recommended only in special cases and then only for a short period of time. The community that is eventually established must be able to persist under the prevailing climatic conditions. Therefore, water-collecting measures, such as contour furrowing, gouging, and pitting, and water-conservation measures, such as mulching, are preferred over irrigation. Irrigation is a recommended practice in arid regions with less than 25 cm (10 in.) of annual precipitation, providing sufficient supplies of water are available. Only enough water should be applied to secure vegetation establishment. Irrigation should be reduced during the second growing season and discontinued in subsequent years. Two types of irrigation systems useful in revegetation efforts are drip and sprinkler.

Drip irrigation systems use less water but are more expensive and less flexible than sprinkler systems. Basin or flood irrigation systems generally are of little use in revegetating surface-mined areas.

In many areas it is also necessary to protect the site against livestock, wildlife, or human traffic. If the planted species are highly attractive to animals, it may be necessary to keep the animals out by fencing or by protecting individual woody plants by wrapping the stems in plastic or metal. Access routes can be barricaded to protect the site from vehicular traffic. However, it often is difficult to completely exclude off-road vehicles.

The site should be monitored annually, or even more often, for insect and disease outbreaks. If these become serious enough, it may necessary to apply recommended insecticides or fungicides.

COVER MAINTENANCE

Following the initial establishment period, the vegetation should be checked to determine if cover and seedling survival are sufficient. Soil samples should be collected from areas with insufficient vegetation and sent to a soil testing laboratory for analysis. Areas with inadequate cover should be limed and fertilized, if needed, and reseeded or replanted with tree or shrub seedlings. Even on areas with adequate vegetative cover, soils should be sampled every four to five years to identify and correct nutrient deficiencies before the cover begins to deteriorate.

6.6.7 Revegetation Case Study

ALTEN F. GRANDT

EDITOR'S INTRODUCTION

The following case study was provided by Alten F. Grandt, Director of Reclamation, Peabody Coal Co. The study was performed to determine if partially reclaimed mine land in Illinois could have its productivity raised by further reclamation treatment. After mining, the land was graded and seeded for use as pastureland. The experiment introduced topsoil onto the graded land two decades after mining. Yields

on the experimental plots were virtually indistinguishable from those on reference plots.

The case study is included here for two reasons. The first is to demonstrate that, with time and care, mined agricultural land can be made to produce the highest yield of row crops. The second reason is to give readers a model of a demonstration that can be used by producing companies when their ability to reclaim agricultural land is in question.

(A) **Purpose:** To measure the effect of topsoil on graded, surface-mined land and to compare corn and soybean (row-crop) yields on original soil and graded surface-mined lands.

(B) Site Characteristics

1. Location: Salem Township, Knox County, Illinois, 1974-1980.
2. Mine type: Area surface mine, Illinois No. 5 coal; overburden consisted of loess, Illinoian glacial till, and unconsolidated shales; maximum depth, 21 m (70 ft).
3. Operation: Mined 1954 and 1955 with Marion 30.6-m³ (40-cu yd) shovel (pre-law). Graded in 1955 with D-7 and D-8 dozers, no topsoil. Seeded in 1955 with disk, broadcast seeder, and harrow (one operation). Species seeded, alfalfa, 5.4 kg (12 lb) per acre, bromegrass, 2.3 kg (5 lb) per acre.
4. Interim Use: Cut for hay and/or grazed by livestock (cattle).
5. Study: Determine the value of replacing topsoil for row crops (corn, soybeans) on graded, surface-mined land.
6. Treatment: 30 cm (12 in.) A horizon (Ipava silt loam) hauled with WABCO D-111A, self-loading scraper, placed on 20-year-old graded area. Graded area chisel plowed 23 cm (9 in.) prior to topsoil application.

(C) Soil test

		kg per ha	
	pH	P2(Bray)	K
1. Ipava silt loam, 1974	6.3	103	104
2. Topsoil on graded spoil, 1974	5.1	154	210
3. Graded spoil, 1954	7.3	176	201
1974	7.5	217	217

(D) Fertility treatment

1. Corn 100-60-60
 2. Soybeans None
 3. Herbicide and insecticide Normal rates as on adjacent farm land.
- Corn: Atrazine-Lasso Beans: Treflan

(E) Corn Yield

	5-yr avg. (1975-1979)	Range of observations, Bu/Ac	
	Bu/Ac	Lowest	Highest
1. Ipava silt loam (ref. area)	139.8	104	168
2. Topsoil on graded spoil	125.5	101	164
3. Graded spoil only	84.6	67	119

(F) Soybean Yield

	3-yr avg. (1978-1980)	Range of observations, Bu/Ac	
	Bu/Ac	Lowest	Highest
1. Ipava silt loam (ref. area)	39.7	24.6	51.0
2. Topsoil on graded spoil	39.9	32.4	46.5
3. Graded spoil only	28.6	22.9	37.0

6.7 Water and Air Management

6.7.1 Water Management

F. A. MEEK, JR.

Introduction

The role of water management in the surface mining industry has changed dramatically in the past 25 years. Proper management and conservation of a mining area's water resources have always received some consideration in the design and implementation of surface mining operations. However, laws passed and regulations implemented in recent years have increased the need for more sophistication in the role of water management.

In the early years of surface mining, water management was primarily concerned with the operational aspects of mining. In the eastern mining regions, where annual precipitation is in excess of 88.9 cm (35 in.) per year, the primary concerns were to provide collection and conveying systems to prevent precipitation and ground water from flooding out or adversely affecting operations. In the western areas of the country, where mining is primarily conducted in arid regions, the primary water management was to conserve and store precipitation for future operational uses.

The operational uses of water at surface mining operations are diverse and dependent on the size of the operation, geologic conditions, and the characteristics of the material being mined. However, the major categories for water usage are as follows: (1) dust control; (2) product preparation; (3) potable and sanitation purposes.

Dust Control

In recent years, products have been made available that reduce the amounts of water required to provide adequate dust control for surface mine haulage ways. However, one of the primary operational requirements for water remains in the area of dust control. The control of dust in pits, haulage routes, preparation operation, and on material conveying systems is required for the safety and health of employees and the overall efficiency of the operation. The primary method for controlling dust in these situations is by the use of both mobile and stationary water spraying systems.

Product Preparation

A primary concern in the development of major operations is the availability of an adequate water supply to provide product preparation. In both coal mining in the East and hard rock mining of ore bodies in the West, the primary cleaning processes are normally by some form of heavy media separation or flotation. In heavy media separation, large amounts of water are mixed with a heavy media substance (magnetite, sand, etc.) and the resulting suspension is adjusted to have a specific gravity that falls between the product being produced and the waste material associated with the material being mined. In flotation, finely ground particles are suspended in quantities of water and selectively floated. Most of the newer coal and all ore preparation plants are designed to reuse the large amounts of water required for processing, but water loss due to surface moisture on and absorption in the products still requires a large makeup water supply. In some cases, the feasibility of mining an area is dependent on the availability of water for product preparation.

Potable and Sanitation

Most surface mining operations today provide bathing and sanitation facilities for employees. Health departments in most states require that water provided for drinking purposes comply with regulations set forth for noncommunity public water supplies. This requires that proposed water supplies must be tested for primary and secondary contaminate levels prior to approval for use. Depending on the source (ground or surface water), before water is considered potable, it must be flocculated, filtered, and chlorinated (with a minimum of 30 min of chlorine contact time). Since there are many variations in raw water sources and governing regulations throughout the country, it is recommended that the state and county health departments be contacted prior to the design of any mine-related drinking water supply.

In developing surface mining operations, the mine planning engineer must carefully evaluate the water requirement against the water availability of the proposed site. The method for evaluation is normally by development of a water budget, shown in Table 1.

The water budget shown in Table 1 indicates that under average conditions, the water supply is adequate for the needs of the operation. However, in addition to a yearly budget, monthly requirements and availability should also be assessed in the designing process. In most situations, water requirements are higher during periods of low precipitation. In addition, the drought frequency of an area should be considered. For areas with low water availability, storage and impoundment facilities can be utilized to distribute supplies over the low precipitation periods.

SURFACE MINE PLANNING AND PERMITTING

With the passage and implementation of the Clean Water Act and subsequent amendments and, more importantly, the Surface Mining Act of 1977, performance standards dealing with the protection of ground and surface water systems were implemented. The Clean Water Act primarily deals with the regulation and enforcement of water quality standards for mine discharges and receiving streams. The Surface Mining Act (PL 95-87) has resulted in regulations that cover virtually all phases of surface mining operations. The Act is primarily oriented to regulate the coal surface mining industry, but many standards set forth have been adopted by state regulatory agencies dealing with the surface mining of materials other than coal. The impact of this legislation on the role of water management in surface mining has been significant.

The portion of the Act dealing with water management is as follows:

Protection of the Hydrologic System: The permittee shall plan and conduct coal mining and reclamation operations to minimize disturbance to the prevailing hydrologic balance in order to prevent long-term adverse changes in the hydrologic balance that could result from surface coal mining and reclamation operations, both on- and off-site. Changes in water quality and quantity, in the depth to ground water, and in the location of surface water drainage channels shall be minimized such that the postmining land use of the disturbed land is not adversely affected and applicable federal and state statutes and regulations are not violated. The permittee shall conduct operations so as to minimize water pollution and shall, where necessary,

Table 1. Example Water Budget

Operational Requirements**Material Preparation**

Total water requirement = 7000 gpm
 Water recycle = 98%
 Water loss = 2%
 Preparation plant operating time = 14 hr per day; 240 days per year

Total usage rate = 7000 gpm \times 14 hr per day \times 60 min per hr
 \times 240 days per yr = 1.4×10^9 gal per year

Water recycle = 1.4×10^9 gal per year \times 0.98 = 1.37×10^9 gal per year

Water loss = Water uptake requirement = 2.8×10^7 gal per year
 1.17×10^5 gal per day

Dust Control

Haul road requirement* = 2 gal per linear ft per day
 Haul road length = 7800 ft
 Haul road requirement = 2 gal per linear ft per day \times 7800 linear ft
 \times 240 days per year = 3.7×10^6 gal per year

*Water requirements for haul roads are dependent on traffic conditions, weather, and road surface qualities.

Potable and Sanitation Requirements

Number of people employed = 226
 Shower and drinking requirements = 62 gal per man per day
 Sanitary facilities = 10 gal per man per day
 Potable and sanitation requirements = 226 men per day \times 72 gal per man per day
 \times 240 days per year = 3.9×10^6 gal per year

Total Water Requirements for Operation

Material preparation = 2.8×10^7 gal per year
 Dust control = 3.7×10^6 gal per year
 Potable and sanitation = 3.9×10^6 gal per year
 Total = 3.6×10^7 gal per year

Water Availability**Surface Water Sources**

Source No. 1: A 3 sq mile drainage area
 Source No. 2: A 1.2 sq mile drainage area
 Average runoff = 6 in. of precipitation per year
 Surface water available = 4.2 sq mile \times 640 acre per sq mile
 \times 0.5 ft \times 325829 gal per acre-ft
 = 4.4×10^8 gal per year

Ground-Water Source

Source No. 1: A well with a yield of 3.5 gpm
 Ground-water available = 3.5 gpm \times 5.2 \times 10^5 min per year
 = 1.8×10^6 gal per year

use treatment methods to control water pollution. The permittee shall emphasize surface coal mining and reclamation practices that will prevent or minimize water pollution and changes in flows in preference to the use of water treatment facilities. Practices to control and minimize pollution include, but are not limited to, stabilizing disturbed areas through grading, diverting runoff, achieving quick growing stands of temporary vegetation, lining drainage channels with rock or vegetation, mulching, sealing acid-forming and toxic-forming materials, and selectively placing waste materials in backfill areas. If pollution can be controlled only by treatment, the permittee shall operate and maintain the necessary water-treatment facilities for as long as treatment is required. (Anon., 1977.)

In addition, the Act breaks down the requirements for the protection of the hydrologic system in the following categories and describes specific requirements and procedures:

- (1) Water quality standards and effluent limitations
- (2) Surface-water monitoring

(3) Diversion and conveyance of overland flow away from disturbed area

- (4) Stream channel diversions
- (5) Sediment control measures
- (6) Discharge structures
- (7) Acid and toxic materials
- (8) Ground water
- (9) Water rights and replacement
- (10) Alluvial valley floors west of the 100th meridian west longitude
- (11) Permanent impoundments
- (12) Hydrologic impact of roads
- (13) Hydrologic impact of other transport facilities

The Act has primarily been a guidance document, providing for standardization of individual state surface mining regulatory agency's procedures and programs. Therefore, there may be some variations between individual state regulatory programs, but these variations are normally not sig-

nificant. To summarize, this legislation requires that, prior to approval to conduct surface mining, the operator must first determine the "probable hydrologic consequences" of mining. To make this determination the following steps must be taken: (1) evaluate the surface and ground-water systems in both the areas being mined and adjacent areas in regard to quantity and quality; (2) evaluate overburden and spoil materials to be mined in regard to their acid, toxic, or alkaline forming characteristics; and (3) design and conduct surface mining operations so as to minimize pollution or quantity changes to both ground- and surface-water systems.

To implement and enforce the provisions of the Act (PL 95-87), the Office of Surface Mining was established within the Department of the Interior. In order to establish guidance and uniformity in the development of these hydrologic investigations, a document was prepared by the Office of Surface Mining entitled, Part 1 "The Determination of the Probable Hydrologic Consequences" and Part 2 "The Statement of the Results of Test Borings or Core Samplings." The document and Act do not specifically mandate the procedures for making the required investigations. However, the document does provide guidance.

In the early stages of mine development in the state in which the mining is to be conducted, the surface mine regulatory authorities should be called in to discuss the methodology for assessing the premining hydrologic conditions for the site. The success or failure of a reclamation plan in regard to the protection of the hydrologic system cannot be evaluated if the premining conditions of the area are not known. A hydrologic investigation and determination should be thoroughly planned and executed. Suggested methodology for conducting an investigation follows.

Area of Investigation

Laws require that hydrologic protection must be provided for both the area to be mined and any downstream adjacent areas that could be affected. It is therefore recommended that the premining hydrologic investigation cover not only the mining area, but also adjacent areas that may be affected.

Premine Surface Water Quantity/Quality Investigation

A surface water monitoring program should accurately define the premining quality and quantity condition of streams and drainways on the mining area and downstream to at least the first receiving stream. The locations of sampling points should be placed on reference maps with coordinates of all locations for future reference. Monitoring points should bracket the mining area with points both above and below the proposed mine area. The sampling frequency should be at a minimum of once per month for a period of six consecutive months. Quantity of water is an important part of the investigation. One full year of consecutive monthly samples would, therefore, more accurately reflect flow conditions during seasonal fluctuations.

Water sample collection should be conducted in accordance with ASTM or standard method procedures. The samples should be analyzed in the field for pH, temperature, and specific conductance. Laboratory analysis should include total dissolved solids, suspended solids, metals normally associated with mining being conducted, dissolved oxygen, sulfate, alkalinity, and acidity. Flow measurement at all sampling points should be taken at corresponding sampling times. Flow measurement should be conducted by an approved method such as weirs, flumes, stream cross sections, staff gages, etc.

The premining monitoring program for surface drainage should also include quality and quantity analysis for both

peak and low flow conditions. During periods of low and high flow, the aquatic and plant life of streams receive the most stress due to elevated stream temperatures and increases in dissolved constituents and the deposition of sediments in streambeds.

Biota Sampling

A premining surface water investigation should include a sampling of biota for streams within and adjacent to the area to be mined. Sampling should be conducted during periods of low flow, if possible. The analysis should include identification of species, diversity, and density. A determination of stream biomass should be obtained for a unit area of the stream. The biota sampling should be conducted at a time corresponding to quantity and quality analysis. Physical conditions, such as stream width, depth, riffle/pool, and bottom type (gravel, boulder, etc.), should be recorded at the time of sampling.

Ground-water Monitoring Program

Premining ground-water conditions also must be evaluated in order to predict the probable hydrologic consequences of mining. The frequency of analysis and parameters analyzed for ground water should parallel those described under surface water investigation. In addition, a depth to water measurement should be taken when quality samples are pulled. At least twice during the monitoring period (preferably during low flow conditions), ground-water monitoring wells should be tested for yield and transmissivity.

The location and number of monitoring wells required to accurately determine ground-water conditions is dependent on the geologic conditions of the site. If only one aquifer is encountered in the mining area, the number of wells would be much less than if several aquifers are present. When the stratigraphy and ground-water location is not well known, it is often necessary to drill an observation hole to identify aquacludes, aquifers, stratigraphy, etc., before a ground-water monitoring program can be designed and implemented. In general, a ground-water monitoring program should include an observation well in the following locations: (1) in each major aquifer to be disturbed in the mining operation within the mined area, (2) in the first aquifer below the seam to be mined within the mined area, (3) in each major aquifer upgradient and adjacent to the mined area, and (4) in each major aquifer and the first aquifer below the seam to be mined down gradient and adjacent to the mined area. When the materials or seams proposed to be mined are located above drainage, springs may sometimes be used as observation points as opposed to wells. Physical information recorded for observation points should include location (coordinates), date drilled, driller, stratigraphy log, depth of hole, diameter of hole, depth to water, and casing details (type, diameter, perforations, etc.).

The surface and ground-water premining water quality investigation programs should be designed around the needs and conditions of the area being mined. In eastern areas of the country where the deposits primarily being mined are located above drainage, the aquifers encountered in the mining process are normally small in size and have limited usage. The topography of eastern mining areas and the high yearly precipitation make mining conditions such that surface water streams and drainways are normally in close proximity to areas being mined. These conditions would require that much more emphasis be placed on conducting an adequate surface water monitoring program rather than a ground-water monitoring investigation. In the western and midwestern areas of the country where mining is normally conducted in flat

and arid or semiarid regions, perennial surface water drainways normally are not in close proximity to the mined areas. These regions, however, normally have large regional aquifers that are the primary sources of water for industrial, agricultural, and potable purposes. When these aquifers are encountered in the mining process, the need for a detailed ground-water hydrologic investigation is a necessity.

Statement of the Results of Test Borings or Core Samples

In order to predict and minimize the probable hydrologic consequences of surface mining, the physical and chemical nature and reactions upon weathering of the overburdens and spoils to be disturbed in the mining process must be evaluated. The earth's surface is in a continual state of weathering. Mountains are eroded by precipitation, wind, and other naturally occurring phenomena. Minerals are dissolved and transported by ground and surface water systems. This process is extremely slow and significant changes in both topography and surface and ground-water systems normally take millions of years to occur. Therefore, the topography, geology, surface and ground-water systems of a proposed surface mining area are in a relatively steady-state condition prior to mining. Ground-water courses and flow paths are well established and reactions that determine the water chemistry are occurring at a steady-state rate to produce ground-water quality that is relatively constant.

During the surface mining process, the rock and earth material (overburden) above the deposit being mined is broken up, excavated, and replaced back on the mine site. This results in new ground-water flow paths in the reconstructed backfills. When the overburden is fragmented, new reactive surfaces for rock/water contact in the backfill are created. It is therefore essential to know the physical and chemical nature of overburdens and other material encountered in the mining process. Because surface and ground-water systems are interconnected, this is essential in any area of the country.

Overburden sampling is normally accomplished by one of the following methods: (1) continuous cores, (2) highwall sampling, and (3) collection of rotary drill cuttings. The most effective sampling is, by far, the use of continuous cores. In this technique, the stratigraphy of the area is well defined. Unweathered samples, precise thickness, and accurate physical qualities of the overburden to be encountered can be obtained. In areas where previous mining has occurred and highwalls are not backfilled, highwall sampling sometimes can be used. In this technique, samples are chipped away and stored for analysis from the various strata above the deposit being mined. This technique can provide general overburden information for the area to be mined. However, because of the difficulty in collection of representative samples, the weathered nature of most highwalls, and the variability in overburdens from site to site, this method has limited applications. An overburden sampling technique that is better than highwall but less optimum than a continuous core is the use of rotary drill cuttings. In this technique, a production drill is set up on the proposed mining area at a predetermined location. The dust curtain on the drill is pulled up enough to enable a shovel to collect drill cuttings blown out the top of the hole. The drill steels are marked in 1.5 to 3-m (5 to 10-ft) increments, and samples are collected and identified according to their depth from surface. Care must be taken to clear the hole of all cuttings between sample increments. This technique provides unweathered samples for laboratory analysis, but the physical nature and stratigraphy of the overburden is difficult to determine using this method.

raphy of the overburden is difficult to determine using this method.

The ideal location and number of overburden test holes is dependent on the geology of the area and the nature of the deposit to be mined. In areas where previous mining has occurred with no adverse impacts on ground or surface water systems, one overburden test site may be adequate to confirm reaction characteristics. However, in areas where mining has occurred with adverse effects, no previous surface mining has occurred, or overburden characteristics are known to vary over short distances, more drilling and sampling will be needed. In these areas, three holes for every 40.5 ha (100 acres) to be mined will normally confirm overburden characteristics or define the need for more drilling.

Test holes should be drilled in locations that will allow collection of overburden samples for all materials encountered in the mining process. Spacing of holes should be such that the distribution of data is optimum.

Locations of test holes or other sampling points should be located by survey (x,y,z coordinates) and placed on maps for future reference. Suggested information to be recorded in the field while drilling is being conducted is as follows:

- 1) Site identification number
 - 2) Date drilled
 - 3) Driller name/company
 - 4) Logged by
 - 5) Weather conditions
 - 6) Stratigraphy including height, general rock type, mineralogy, grain type/size, matrix, reaction to HCl, presence of any staining, and hardness
 - 7) Location of ground water encountered during drilling
- Overburden sampled by coring, highwall, or production drill methods should be stored in a manner that provides protection from weathering, easy identification, and compact storage.

Preparation of Samples For Analysis

Proper preparation of overburden samples is very important in obtaining accurate data on the acid/base reaction nature of material encountered in the surface mining process. The expense of site preparation, mobilization, and drilling will be wasted if the preparation of the samples obtained is not handled correctly. Continuous core samples should be prepared according to stratigraphy. Each individual strata of the column should be separated and the entire strata crushed to 9.5 mm ($\frac{3}{8}$ in.) \times 0. When strata thickness exceeds 3 m (10 ft), the sample should be crushed in 3-m (10 ft) increments. If rock durability analysis is to be performed on the material, a 76.2 to 152.4-mm (3 to 6-in.) section of the strata uncrushed should be retained. Once the sample is crushed, it is split by *cone and quartering*, or other standard methods for sample preparation, into four approximately equal samples. One of the four samples is further pulverized to less than 75 μ m (200 mesh) for acid/base accounting, petrographic examination, and other analytical procedures. The remaining samples are retained for simulated weathering tests and for a reserve. Highwall and production drill samples should be prepared for analysis in the same manner. However, the sample size and location are predetermined at the time of collection for these techniques.

Overburden Analytical Testing Procedures

In order to predict or determine what spoil/water reactions will occur on reclaimed surface mine sites, analytical procedures have been developed to help indicate the acid/

base properties of overburdens and mine spoils from core borings and other sampling techniques. The most commonly used procedure is termed *acid-base accounting* ("Field and Laboratory Procedures for Overburden and Mine Spoils," EPA publication). In this procedure, the samples are analyzed for their maximum acid-producing potential and the amount of neutralizing potential (alkalinity) present.

Acid-base accounting includes three analytical procedures performed on each sample tested: total sulfur, calcium carbonate equivalents, and paste pH. The total sulfur analysis is performed to give the maximum amount of pyrite (FeS_2 acid-producing) that will be present in the sample. The analysis is performed by heating a pulverized sample to temperatures hot enough to liberate SO_2 . The SO_2 is then oxidized to H_2SO_4 and back titrated to give the sulfur contents of the sample. This is done with the same type of sulfur analyzer used in the analysis of sulfur in coal. The calcium carbonate equivalents are found by placing a pulverized overburden sample in hydrochloric acid and water and heating the sam-

ple until all alkaline materials present have reacted with the HCl. The sample is then back titrated and the amount of calcium carbonate (CaCO_3) equivalents present in the sample is calculated. The paste pH test is accomplished by making a paste of the overburden sample and distilled water and measuring the pH of the mixture. This procedure is intended to give information on the current acid-base state of the sample, rather than how the sample will react in the future.

In the acid-base accounting, the results of the acid-producing (*T. Sulfur*) and alkaline-producing (CaCO_3 equivalents) tests previously described are reported in CaCO_3 equivalents. The acid-producing nature is expressed in tons CaCO_3 needed per 1000 tons of material, and the alkaline-producing nature is expressed in tons CaCO_3 present per 1000 tons of material. By comparing these two values of an overburden sample, the overall alkaline or acidic nature of the material is determined.

An example acid-base accounting report form will help demonstrate the concept.

Example

Hole ID — DDH 514
Longitude —
Latitude —
Surface elevation — 617.5 m (2026 ft)

No.	Sample ID (ft)	Rock Type	Fizz	pH	T. sulfur	St CaCO_3 per 1000 St Material			
						CaCO_3 Present	Max CaCO_3^* Requirements	Amt. Need	Amt. Excess
1	26.2–32.3	Brown shale	0	6.5	0.60%	5.4	18.75	13.35	
2	32.3–45.0	Gray sandstone	1	6.5	0.10%	24.3	3.125		21.18

*Maximum needed is obtained by multiplying the percent sulfur of the sample by 31.25.

Metric conversions: ft \times 0.3048 = m; st \times 0.907 184 7 = t.

The preceding example shows that sample No. 1 has more acid-producing capabilities than alkaline material present. For the sample, 13.35 tons of CaCO_3 (limestone) would be needed to make 1000 tons of the material neutral. Sample No. 2 has an excess above neutral of 21.18 tons of CaCO_3 per 1000 tons of material present. It has been suggested that a sample must have 5.0 tons CaCO_3 per 1000 tons material or more in the amount needed column before it should be considered acid-producing. However, this cannot be assumed to hold true in every case. Samples that are relatively neutral

(between 5 ton per 1000 tons needed and 5 ton per 1000 tons excess) by acid-base accounting procedures should be further evaluated by analyzing for forms of sulfur or simulated weathering tests.

When the acid-base accounting tests have been performed, this information should be integrated with the individual strata volumetrics of an area to be mined to see the overall acid-base materials balance. An example of this process is shown as follows:

Strata ID (ft)*	Volume	Density	Total Tons	Tons CaCO_3 /1000 Ton Materials		Total CaCO_3 /Strata	
				Excess CaCO_3	Amt. Needed	Needed	Excess
26.2–32.3	600 acre-ft	150 pcf	1960200		13.35	26168.7	
32.3–45.0	1000 acre-ft	146 pcf	3179880	21.18			67350

*Metric equivalents: ft \times 0.3048 = m; acre-ft \times 1233.489 = m^3 ; pcf \times 16.018 46 = kg/m^3 ; st \times 0.907 184 7 = t.

By conducting the foregoing exercise for all materials encountered in the surface mining process, the overall acid-base nature of the overburden is assessed.

Simulated Weathering Tests

When acid-base accounting tests indicate that materials are relatively neutral, simulated weathering tests can be per-

formed to quantify the acidic or alkaline nature of the individual strata. Specific procedures are outlined in Sobek (1978). In general, the tests are designed to subject the materials tested to conditions that are similar to those of a surface mine backfill. Samples of the individual strata are crushed to 6.35 mm ($\frac{1}{4}$ in.) \times 0 size. Three to five hundred grams (10.6 to 17.6 oz) of sample is placed in a simulated

weathering cell. The cell is normally a glass or plastic closed container, measuring approximately $203.2 \times 203.2 \times 101.6$ mm ($8 \times 8 \times 4$ in.) in size, fitted with one hole near the top and one hole near the bottom of the container. The sample is initially wetted and both humid and dry air is passed over the sample (via a mechanical air pump) for three-day periods. On the seventh day, the air is turned off, the holes are plugged, and 200 to 500 mL (6.8 to 16.9 oz.) of distilled water is poured into the container and allowed to stand for 1 hr. The water is then drained off and collected for laboratory analysis. The suggested analyses to be performed are volume, pH, total alkalinity, total acidity, total iron, total manganese, and specific conductance. Simulated weathering tests have been recommended to run from 7 to 15 weekly cycles.

In addition, to determine the acidic or basic nature of relatively neutral samples, this procedure reflects the rate at which acidity or alkalinity will be produced. Caution should be used, however, in using this information to predict specific rates of alkalinity or acidity that a mine site will produce in drainage. Due to the inconsistent size gradation of overburden and mine spoils and the effects of adjacent overburden on an individual strata's reaction rates, predictions that deal with specific quantities or qualities are likely to be incorrect.

The analytical procedures previously described deal with identifying the acidic and alkaline characteristics of individual stratas. The surface mine backfill consists of a conglomeration of these individual stratas determined by the topography, geology, equipment, and method of operation used to mine the area. The effects of this strata mixing can alter the overall acid-base reactions of the individual strata from those reflected in the sampling and analysis procedures. Simulated weathering tests can be designed to account for this mixing effect if the sequence of overburden removal can be predetermined. By combining individual strata samples in the same proportion that they will exist on the mine area backfill, this combining effect can be assessed. In addition, the quality of water moving through a surface mine backfill can affect the acid-base reaction mechanisms.

Predicting the Hydrologic Consequences of Surface Mining

The investigations described earlier for both surface and ground water systems are intended to show the surface mine operator the quantity and quality of the systems present on the proposed mine area. The overburden testing procedures described indicate the presence or absence of acidic or alkaline producing compounds associated with the materials to be disturbed during the surface mining process.

In general, the areas to be addressed in predicting effects on ground water systems are: transmissivity, storage coefficient, aquifer yields, water quality, ground water/surface water hydrologic balance, and usage of ground water in the area to be mined. In the surface mining process, the ground water systems located on the mine site above the deposits being mined will be removed. After mining and reclamation is complete, the ground water systems will reestablish. The changes in ground water systems from premining to postmining are normally dependent on changes to fracturing of previously stratified rock; removal of aquacludes; increasing or decreasing infiltration rates; increasing or decreasing discharge rates to surface water systems; and increased surface area and reaction surfaces for water-rock contact.

In mining areas where ground water systems consist of multiaquifers that support commercial and/or residential use, investigations will normally require the aid of computer

models that simulate ground water flows and quality according to conditions. In any event, the exercise will require expertise in geology, hydrology, chemistry, and mining engineering. In many cases, the effects of surface mining on ground water systems may be beneficial in the areas of well yield, storage capacity, and quality. The amount of investigation required to adequately predict the results of mining should correspond to the presence and usage of ground water systems on a proposed mine area.

Primary areas to address when predicting the effects of surface mining on surface water systems are: (1) changes in stream flow quantities, (2) channel stability, (3) erosion and sediment yields, (4) water quality, (5) aquatic biota, and (6) ground water/surface water hydrologic balance. Sedimentation and erosion controls that adequately protect streams located down gradient from surface mining operations have been in use for many years. Stream channel protections have been accomplished throughout the country by the use of riprap, levees, and vegetation. Surface mined areas normally have elevated infiltration and ground water storage coefficients, in comparison to premine conditions that generally help stream flow and hydrologic balance conditions by reducing peak flow conditions and increasing base flow conditions.

By far, the most difficult task in the area of hydrologic protection for surface mine operations is in the area of water quality protection. When surface mine overburdens do not contain alkaline or acidic-forming compounds, operational design can concentrate on efficient overburden removal, materials handling, and backfilling. However, when polluting materials are prominent in the overburdens, operations must be designed to minimize the production and transport of pollutants in the hydrologic regime. Unlike sediment control and stream stability measures, these techniques are site specific and dependent on the individual condition of the site. These preventative techniques are the result of a currently active research effort that will continue to expand the technology. The procedures should be considered state-of-the-art, but are not yet considered accepted design practices throughout the country. Because of the need of many operators throughout the country to know how to handle polluting overburdens, the primary techniques in use are discussed.

POLLUTION PREVENTATIVE MINING TECHNIQUES

Blending of Overburdens

In proposed mining areas where the ratio of potentially polluting to nonpolluting overburdens is low, blending is often used to avoid water quality problems. Studies have indicated that when polluting material constitutes 5% or less of the total overburden, dilution normally provides enough control to minimize water quality problems. Blending techniques coincide particularly well with surface operations utilizing draglines as the primary excavators. In operations using shovel/loaders and trucks, more design is needed to assure a thorough blending of materials.

In mine areas where the polluting materials present are disulfide minerals (acid-producing), blending can act as an acid preventative mechanism rather than just dilution. Alkalinity, if present in enough quantity, in a spoil system inhibits disulfide oxidation. When overburden acid/base analysis and stratigraphic volumes determine that the total overburden has in excess of 20 tons CaCO_3 per 1000 tons of material, blending can be an effective acid preventative

technique. It is important to realize that the neutrality of the total overburden, in regard to acid-base and volume analysis, does not assure that blending will prevent acid mine drainage from occurring. The solubility of CaCO_3 is limited under atmospheric conditions and disulfide oxidation is enhanced when exposed to air and water (atmospheric conditions). This unbalanced reaction rate results in a system being acid producing when alkaline and acidic components are theoretically neutral. However, when alkaline components are significantly in excess (20 tons CaCO_3 per 1000 tons material), both neutralization and reduction in disulfide oxidation occurs if the materials are thoroughly blended. In areas where the alkaline components of overburden are more soluble than limestone, less excess alkalinity is needed. Simulated weathering tests should be conducted on overburden from the proposed mine site to assess alkaline/acid reaction rates on the blended materials. When the amounts of polluting material present in overburden is significant, blending is not an applicable preventative technique. In these cases, selective handling and placement of polluting materials may be required.

Selective Handling and Placement

A method used in the mining industry to minimize the transport of soluble salts from the oxidation and/or solubilization of polluting materials associated with fragmented overburden is the use of selective handling and placement. The technique involves:

- 1) Identification and location of polluting materials in the overburden or spoil to be disturbed in the mining process.
- 2) Designing the removal and placement of such material in a manner as to minimize its contact with ground or surface water flows. Designing the removal and placement of such material as to minimize oxidation of pyritic (acid forming) compounds in the mined material.

The identification of the polluting material was described earlier in the "Statement of the Results of Test Borings or Core Samplings." A graphic depiction of the results of such analysis is shown in Fig. 1.

Fig. 1. Stratigraphic column.

Once materials are identified, the task of designing removal and placement plans can be developed. When surface mine overburdens and spoils are drilled, shot, and excavated in the mining process, the surface area of the materials is greatly increased. Unweathered alkaline and acid-producing compounds associated with these freshly exposed surfaces are now capable of contacting air (oxidation) and water (transport). As a result, the weathering products can enter into the ground and surface water by stems. In a surface mine backfill, the porous nature of the backfill material makes it extremely difficult to exclude air from the system. Changes in barometric pressures can cause air movement in and out of what appears to be very compacted backfills. However, if polluting materials are selectively removed and placed in areas that will not come in direct contact with water, the pollutants are not transported into the hydrologic system. Figs. 2 through Fig. 5 are graphic examples of how selective handling and placement can be used on a contour surface coal mining operation. In this example, the relatively steep outslopes of the regraded will promote surface runoff as opposed to infiltration. With the placement of the coarse nontoxic material against the highwall and on the pit floor, ground water is directed away from the toxic material, thus preventing transport of weathering products.

In areas of the country where the materials being mined are located below the ground water table, another form of selective handling and placement is used. In order for pyritic (FeS_2) material to produce acid, it must first be oxidized.

Reaction Process

Oxygen (O_2) is necessary for the oxidation of pyrite to occur. The maximum concentrations of oxygen in water, if not continually replaced, will limit pyrite oxidation. Fig. 6 shows material placement for this form of selective handling. It is very important that toxic materials be placed below seasonal and drought fluctuation in the water table. If toxic materials are temporarily stored out of these reducing conditions, or if the water table buildup over the toxic material takes considerable time, weathering (oxidation) of the toxic-forming compounds could occur. If this should happen, the soluble salt resulting from the oxidation will enter the ground water system.

Sealing Techniques

When topographic conditions of a mine site dictate a gentle or flat regraded slope, much of the yearly precipitation will infiltrate into the porous backfills. If the amounts of potentially polluting overburdens are large and spread throughout the mined area, significant amounts of infiltrating water will contact these overburdens, creating a potential for pollution to occur. By the use of selective handling and placement and subsequent sealing of the surface of potentially polluting materials, the hydrology of the backfill is manipulated to minimize the problem.

Fig. 7 shows a mountaintop situation where selective handling and placement and sealing techniques are used. After product removal, a blanket of porous nonpolluting material is placed on the pit floor. This is done to provide positive drainage for any artesian effects and to support the polluting material above any accumulated water on the pit

Fig. 2. Selective handling and placement. Drainage system is to be installed before mining operations begin.

Fig. 3. Selective handling and placement. First cut.

Fig. 4. Selective handling and placement. Second cut.

Fig. 6. Selective placement and handling, during and after mining.

floor. The potentially polluting material is then placed on the pad and brought to approximate final contour. In this case, the compacted clay seal is placed over the material. To provide positive drainage above the seal and to provide a rooting zone for revegetation, a cover of 1.2 to 1.8 m (4 to 6 ft) of nonpolluting material is placed on top of the seal.

In areas where suitable clay material is nonabundant, other sealing materials such as PVC or polyethylene have been used. It should be noted that this technique is normally only used in areas where the potential for pollution to occur is significant and well defined through a history of mining. The costs of both selective handling and sealing can be extremely high.

Use of Chemical Additives

In recent years, a lot of research efforts have been aimed at the development of a chemical that could be added to potentially acidic coal overburdens to prevent or impede pyrite oxidation.

Research efforts by Singer and Stumm identified the acid production reactions of pyrite as follows:

It was determined that the rate limiting step of this reaction process is the oxidation of Fe^{2+} to Fe^{3+} in reaction 3. The oxidation of pyrite (FeS_2) occurs much quicker when oxidized by Fe^{3+} (reaction 4) than by O_2 (reaction 1). By controlling the Fe^{2+} to Fe^{3+} step, 60 to 95% of the acid normally produced can be eliminated. Several researchers have determined that Fe^{2+} to Fe^{3+} oxidation step is controlled by the bacterium, *T. Ferrooxidans*.

The use of anionic surfactants as a backfill additive has been proposed and used. By spraying a mixture of surfactant and water on to potentially acidic spoils, the population of bacterium is controlled, thus reducing the amounts of acidity produced.

A drawback to this method is the temporary nature of the treatment and the problem potential of overtreatment. Anionic surfactants are water soluble, and will eventually be washed out of the system, allowing the bacterium to repopulate. Some research has been conducted on the use of slow release pellets containing the controlling substance. Tests have indicated the treatment life of the slow release pellets is from two to five years.

The surfactant controls *T. Ferrooxidans* by breaking down their protective outer membrane. Concentrations as low as 25 ppm have been shown to adequately control the bacterium. Most suggested or required stream standards for surfactant concentrations are less than 1 ppm. Therefore, careful evaluation of the spoils adsorption and release capacities and potential adverse effects must be conducted prior to treatment.

Other chemical additives that have shown success in preventing acidic mine drainage in the laboratory and limited field-scale tests are phosphate compounds. Phosphate ions (PO_4) will effectively complex Fe^{++} ions as $\text{Fe}_3(\text{PO}_4)_2$ prior to their oxidation to Fe^{+++} .

Reaction

Fig. 7. Sealing techniques.

By complexing the ferrous ion (Fe^{++}), the phosphate ion has accomplished two significant steps in preventing acid mine drainage. They are (1) preventing Fe^{++} oxidation to Fe^{+++} (established above as the rate limiting step), and (2) preventing one-half of the potential acidity of pyrite from occurring.

The research shows that if the phosphate ions are present, acidities produced from pyrite oxidation are significantly reduced. Several phosphate compounds have been proposed for use as overburden additives. The primary ones are:

- 1) Diammonium phosphate (18-46-0, fertilizer)
- 2) Triple super phosphate (0-46-0, fertilizer)
- 3) Apatite rock

Both diammonium and triple super phosphate compounds are readily available and provide an immediate source of phosphate ions. The relatively high solubility of these compounds provides good mobilization of the phosphate ion to the acid-producing surfaces within a backfill, making the compound ideal for use on previously constructed fills. The high solubility consequently makes the treatment only temporary in nature, unless all reacted surfaces are complexed with the initial treatment. Recommended dosage rates of the compound are dependent on amount of acid-producing material present, adsorption capacity of spoil material treated, and hydrologic conditions of the site. Since these materials are water soluble, care must be taken to prevent PO_4 ions from entering ground or surface water systems. Most states limit discharge concentrations of phosphate because of its eutrophication effects.

Apatite rock ($\text{CA}_3(\text{X})(\text{PO}_4)_3$) ($\text{X} = \text{F}, \text{Cl}, \text{OH}$) is a raw mineral mined and further refined to produce the two phosphate compounds discussed previously. The material is mined and washed to liberate clays from the matrix, resulting in an initial product that ranges from 30 to 45% PO_4 , with a gradation similar to sand. Apatite rock is relatively insoluble except under acidic conditions. This provides control on the release of PO_4 ion into the system, allowing the compound to be inert until acid production occurs. Studies indicate that the optimum application rate is 0.3 tons of 64% BPL (40% PO_4) per 100 tons of acidic material. This is independent of the potential acidity of the material treated. An important factor in obtaining success from this treatment method is a thorough blending of the apatite rock with the material being treated.

A chemical additive that has had the most usage in surface mining for control of acidic drainage is lime (CaCO_3). The bacterium, *T. Ferrooxidans*, that are responsible for the rate-determining step in the overall acid production reaction process, thrive in pH conditions less than 4.5. If pH conditions within a backfill can be kept in a neutral or alkaline condition, the population of bacterium is controlled, thus controlling the acid production. Two basic schools of thought on how best to apply and use lime as an acidic control measure are: (1) topical application over the spoil area and (2) segregation of acidic material and blending of lime within the backfill. Under relatively mild acidic conditions, topical applications may provide enough alkalinity to prevent the acceleration of pyrite oxidation or neutralize what acidity is produced. However, CaCO_3 is relatively insoluble under ambient conditions and mobilization of alkalinity to the acid-producing reaction sites within a fill is limited. By segregating the potentially polluting materials and add mixing lime or other alkaline products to the spoil, more assurance is obtained that the alkaline material is near the acid-producing surfaces.

All of the acid preventative techniques discussed add

significant costs to a surface mining operation. An operator must thoroughly evaluate the mining conditions and polluting potential of the areas to be mined. Current laws require that pollution resulting from mining operations must be treated to acceptable limits as long as the condition exists. Consideration must be given to the costs of long-term treatment as opposed to higher mining cost due to the implementation of an acid preventative technique for the life of the mine.

WATER TREATMENT

In surface mining operations, large quantities of rock and earth material are disturbed from their original consolidated state and exposed to the environment until final reclamation and revegetation of the area is achieved. During this period, the potential exists for large quantities of solids to be transported, via surface water runoff, into streams and waterways. Environmental regulations mandate that (1) water draining from all disturbed areas associated with surface mining must pass through a sediment control structure prior to entering a receiving stream, and (2) the suspended solid concentrations of surface mine discharges cannot exceed a 30 mg/L average or a 60 mg/L maximum concentration for any one-month period (some variations are given under extreme conditions). Regulating authorities require that sedimentation control structures be sized to provide 154.2 to 2467 m^3 0.125 to 2.0 acre-ft of storage capacity per acre of disturbed area (depending on individual state regulatory programs).

For most geologic conditions, this sediment storage volume is more than enough to meet suspended solids effluent limits. However, in areas with high concentrations of clays and other material present in the overburdens, it may be necessary to use chemical flocculants to achieve compliance quality discharges.

Sedimentation from surface mining operations can be controlled by using common sense mining methods and observations. Recommended guidelines and practices are as follows:

- 1) Schedule mining operations in such a manner as to minimize nonstabilized land areas.
- 2) Attempt to limit topsoil removal and replacement to one operation.
- 3) Construct and stabilize control measures in advance of mining operations.
- 4) With the use of diversions, prevent flowing water from entering highly erodable areas.
- 5) Use energy dissipaters to slow down flow velocities in ditches, diversions, etc.
- 6) Inspect and maintain controls after each significant storm event.
- 7) Completely integrate drainage, erosion, and sediment control into every stage of the surface mining operation.

Tables 2 and 3 list the various types of sediment control measures commonly used throughout the industry.

A common water treatment requirement for many surface mining operations is pH adjustment and metals removal. Regulations require that surface mine discharges be within the pH range of 6.0 to 9.0. Various metal ion concentrations for discharges are enforced, depending on the material to be mined. However, the most common requirements are for iron and manganese concentrations associated with acid or ferruginous mine drainage. Even in areas of the country where acid or iron producing overburden is not present, temporary treatment is often required for pit accumulation or product tailings runoff.

When evaluating the water treatments requirement for

an operation in regard to pH and metals control, several factors must be assessed. These factors include longevity of treatment requirement, concentrations and quantities of water requiring treatment, and power and sludge handling requirements.

Longevity of Treatment Required

Surface mining operations normally are continually moving. Areas are disturbed and the products mined are exposed. The area is then backfilled and restabilized. pH and metals removal treatment requirements are often only for a short period of time. Preparation and refuse disposal facilities for operations, however, are normally at a fixed location for extended periods of time.

pH adjustments are achieved by the addition of alkaline reagents to the water being treated. Table 4 shows the most commonly used alkaline reagents for pH adjustments with their cost and neutralization capabilities. The information indicates the most cost-effective compounds are limestone, quicklime, and hydrated lime. However, the solubility of these compounds is much less than the solubility of either caustic soda or soda ash. This requires mechanical agitation of the compounds with the raw water being treated to obtain adequate treatment and reagent utilization. The solubility of the other two compounds shown allows the reagent to be added with no mechanical mixing to achieve proper treatment.

Figs. 8 and 9 show the types of systems most commonly used in conjunction with the reagents discussed. The high solubility of NaOH solutions allows for a simple flow regulation feeding system to be utilized. The system is initially calibrated and feed rates are automatically adjusted for all but extreme fluctuations in raw water flow. An example calculation of treatment cost for the two systems will best

reflect the importance of assessing the longevity of treatment requirements when determining treatment system needs.

Example

Water to be treated

Amount = 567.8 L/min (150 gpm)

Quality = 500 mg/L (CaCO₃ acidity)

Duration of treatment requirement = 2 years

Caustic soda system

Storage tank 11356.2 L (3000 gal) = \$2,500

Feeder system = \$1,000

Installation = \$ 500

Initial cost of installation = \$ 4,000

Operational cost

Chemical cost = \$70,042

Power cost = -0-

Operational labor and repairs = \$ 1,000

Total O and O cost = \$75,042

Hydrated Lime System

Lime storage bin 22.7 t (25 st) = \$15,000

Mix tank; mixer = \$ 3,000

Pumps = \$ 4,000

Lime feeder, bin activator = \$10,000

Installation = \$30,000

Initial cost of installation = \$62,000

Chemical cost = \$ 5,819

Power cost = \$ 2,000

Table 4. Alkali Neutralization Capabilities

Reagent		Neutralizing* Equivalent	Cents/Lb	Cents per Neutralization Equivalent
Limestone	CaCO ₃	8.36	0.23	1.92
Quicklime	CaO	4.67	1.05	4.91
Hydrated lime	Ca(OH) ₂	6.18	1.19	7.35
Caustic soda	NaOH	6.67	13.40†	89.40
			3.90‡	26.02
Soda ash	Na ₂ CO ₃	8.84	3.80	33.58

* Pounds of reagent to neutralize 1 mg/L acidity in 1 million gal of water.

† 50% solution in 55-gal drums.

‡ Flake or pellets in bulk.

Metric equivalents: gal × 3.785 412 = L; lb × 0.453 592 4 = kg.

Fig. 8. Sodium hydroxide feed unit.

Operational labor and repairs = \$ 3,000
 Total O and O cost = \$72,819

Calculation

Quantity to treat = $150 \text{ gpm} \times 525,600 \text{ min/year} \times 2$
 $\text{year} = 1.58 \times 10^8 \text{ total gal treated}$
 Reagent requirement = $1.58 \times 10^8 / 1.0 \times 10^6 \times 500$
 $\text{mg/L acidity} \times \text{neutralizing equivalent}$

hydrated lime = $4.89 \times 10^5 \text{ lb}$
 caustic soda = $5.27 \times 10^5 \text{ lb}$

Reagent cost

hydrated lime = $4.89 \times 10^5 \times 1.19 = \5819.10
 caustic soda = $5.27 \times 10^5 \times 6.67 = \$70,042.00$

This example indicates that the hydrated lime treatment system will provide a slight cost advantage over the less sophisticated sodium hydroxide system. The salvage value of the system may add some additional cost saving. However, for most short duration treatment requirements, the less costly systems provide a better approach.

Quantity and Quality of Water to be Treated

In addition to the longevity of treatment requirements, the quantity and quality of the raw water to be treated must be thoroughly assessed prior to design of any treatment system. Typical acidic mine drainage has various concentrations of metals, in addition to low pH conditions. Table 5 lists various metal ion concentrations from mining operations.

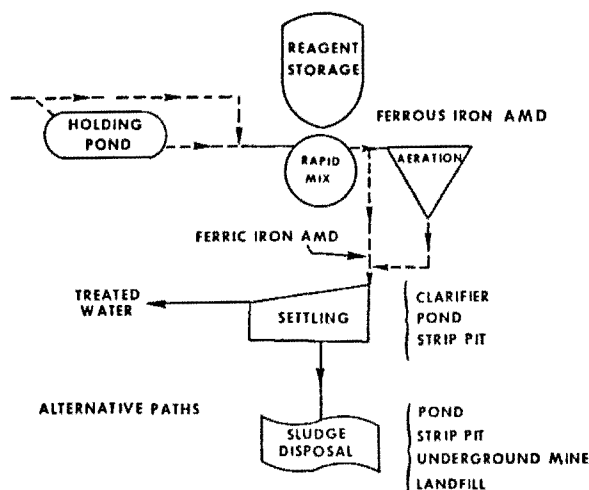

Fig. 9. Flowsheet for solid reagent AMD treatment system.

The most common method of metals removal is obtained by pH adjustment and metal sludge removal. Metal ions solubility is normally associated with the pH of the solution. Figs. 10 and 11 show the effects of neutralization on the primary and trace metal concentrations in solution. Typically, the metal ions are precipitated out as hydroxide compounds as the pH of the raw water is raised.

For example,

As a result, the type and concentration of the metal ions in the raw water to be treated may determine the type of system and reagent to be used. For example, limestone is the most economical reagent available for neutralization purposes. However, Fig. 12 shows that the pH obtained by limestone treatment is not high enough to allow precipitation of metal ions associated with mine waters.

By far the most operationally cumbersome step in the mine water treatment process is the handling of precipitated metal sludges. Once the pH of raw water is treated to the point that metal hydroxide precipitation occurs, a separation of the precipitated material and the clarified water must be achieved. The simplest procedure is to provide settling capacity with the use of ponds or impoundment structures. When precipitation occurs, the metal hydroxide normally has several molecules of water tied up as water of hydration ($\text{Fe OH}_3 \cdot 6\text{H}_2\text{O}$). This results in a very light sludge product that will contain only 5 to 30% solids by weight. The sludges produced are often colloidal in size and may require chemical flocculation.

Prior to design of mine drainage treatment systems, it is necessary to predict or measure sludge production volumes so that settling and handling systems can be designed accordingly.

Sludge production and densities are dependent on type and concentration of metal ions present in the raw water, type of reagent and treatment system used, and the use of mechanical or chemical densifiers.

Fig. 13 shows the densification nature of an example of precipitated metal complex sludge. By running a bench scale neutralization test on the water to be treated (or water that is similar to what is expected) with the neutralization reagent to be used, the initial sludge production can be measured.

Table 5. Selected Mine Drainage Analyses, Mg/L

Example Calculation

Raw water quantity = 150 gpm
 Sludge production = 100 mL sludge/liter
 Initial sludge density = 5% solid (by weight)

Initial Sludge Production
 $3208.5 \text{ cu yd per month} =$
 $150 \text{ gpm} \times 3.785 \text{ L/gal} \times 100 \text{ mL/L} \times 43,200 \text{ min/month}$
 $764,418.6 \text{ mL/cu yd}$

Example Sludge Production Rate (for Six Month Period)
 with Densification Properties According to Fig. 13

Month					
1	2	3	4	5	6
3208.5	2292	1123	943	844	844
	3208.5	2292	1123	943	844
		3208	2292	1123	943
			3208	2292	1123
				3208	2292
					3208

Total volume sludge accumulated 9254 cu yd

*Metric equivalents: gal $\times 3.785412 = \text{L}$; cu yd $\times 0.7645549 = \text{m}^3$.

This example calculation indicates that for the proposed quantity and quality of water tested, 7075 m³ (9254 cu yd) of storage capacity is required to handle precipitated metal sludges for a six-month period of time. In addition, sizing must allow adequate sludge/clear-water freeboard and water velocities to properly separate the solids from suspension.

Handling and disposing of this precipitated sludge is generally accomplished by one of the following methods:

Cleaning Method

1. Clam shell and trucks
2. Endloader and trucks
3. Pumping systems

Disposal Locations

1. Strip pits
2. Refuse disposal areas
3. Abandon underground workings

Typical systems normally have two settling basins constructed for each system. While one basin is being cleaned, the other is in active use. Because of the nature of typical sludges and the problems encountered in handling this material, many installations utilize large impoundments for sludge removal. The structures are sized to handle several years of disposal with the sludge left in place and reclaimed as opposed to continual cleaning.

Fig. 11. Observed solubilities as a function of initial pH (batch studies).

Fig. 12. Titration curve for lime and limestone.

WATER CONVEYANCE AND POND DESIGN

One of the primary functions of the surface mining engineer in the role of water management is the design and proper installation of water conveyance and sediment control structures. The proper sizing and erosion protection of ditch lines, sediment channels, and ponds is essential for water quality compliance and an efficient operation. Open channel conveyance structures and ponds that are undersized could result in overtops that can adversely affect operations (flood active pits) and transport large sediment loads off the mine area.

In the design of open channel conveyance structures, the primary areas of consideration are (1) maximum water flow that will enter the channel, (2) maximum capacity of the channel, and (3) erosion protection of the channel. The factors influencing the maximum flow that will enter an open channel are rainfall, slope of land, and runoff characteristics of the drainage area. Regulatory authorities require that open

channels constructed on surface mines be designed to handle certain frequency storms. Permanent channels may be required to be designed to handle a 100-year frequency storm, while a temporary channel may only have to handle a 1-year frequency event. Fig. 14 shows the precipitation associated with a 5-year 24-hr storm event and the variation within the United States. The runoff characteristics of a drainage area are given by the relationship: (SCS method)

$$Q = \frac{(P - 0.2S)^2}{P + 0.8S}$$

where P is the accumulated precipitation, Q is the accumulated runoff volume (inches), and $S = (1000/CN) - CN$.

CN is known as the curve number and defines the absorption/infiltration/runoff characteristics of soils. The Soil Conservation Service (SCS) has classified over 4000 soils into four hydrologic soil groups. The curve numbers for the hydrologic soil groups with various land use descriptions are shown in Table 6. Some states, in cooperation with SCS, have assigned specific curve numbers for active and reclaimed surface mines. With the curve number and precipitation over time given, the runoff entering a particular open channel can be calculated.

Table 7 shows the effective runoff for a storm event using a curve number of 89. By combining the effective runoff with the area collected by an open channel and the lag time for the runoff to move to the channel, peak channel flow is given. The lag time (time of concentration) is given by the following formula:

$$tc = 0.928 (nL)^6 / ie^{0.4} S^{0.3}$$

where n is mannings, L is feet, ie is inches per hour (excess), S is the slope of land in foot per foot, and tc is minutes.

The result of these calculations is the development of a hydrograph (Fig. 15) that graphically shows the runoff to be handled for a precipitation event.

Because of the complexity of these calculations, most state regulatory authorities have developed technical handbooks that categorize typical drainage conditions to produce graphs that give peak discharge and runoff rates for a number of conditions. Fig. 16 gives peak discharge rates for small wa-

Fig. 13. Example sludge densification.

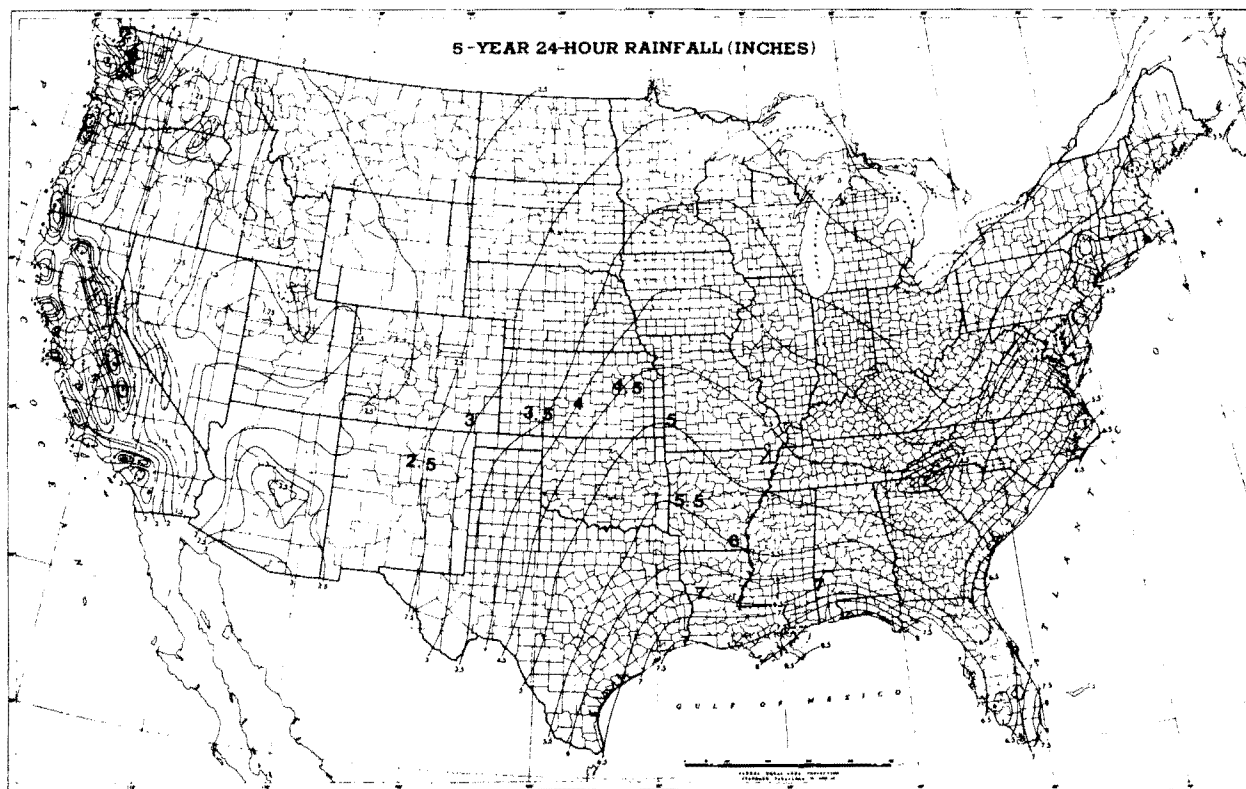

Fig. 14. Precipitation distribution of an event storm.

Fig. 15. Example runoff hydrograph.

tersheds with moderate slope conditions and a curve number of 85 for varying rainfall events.

The capacity of an open channel may be written as $Q = VA$, where Q is capacity in cfs, V is velocity in fps, and A is the cross-sectional area of the channel in square feet. Velocity is given by the following manning equation:

$$v = 1.49 / N R^{2/3} S^{1/2}$$

where N is the manning number (see Table 8), R is feet (length), and S is the slope of channel in feet per foot.

Sediment channel and diversion ditches should be constructed with enough freeboard, above peak flow, to allow for partial sediment buildup.

Once channels are designed to handle anticipated runoffs, consideration must be given to protecting and stabilizing the structure. The erodibility of material the structures are made of and the anticipated water velocities are the principal factors in determining if erosion protection measures should be implemented. Table 8 demonstrates, for various material types, the velocities at which erosion will occur within a channel. When erosion protection must be used, there are several techniques available. The primary techniques used in the industry are jute mesh, vegetation growth, geotechnical fabric, and varying sizes of rock riprap. Fig. 17 shows the effective range of erosion protection of the different techniques over varying flow rates and channel slope conditions.

Sediment control structures (pond, sediment control channel, etc.) have become an integral part of surface mining operations. The structures are required by law to avoid transport of solids from the mining site to stream channels off the site. Proper protection against overtopping and failure of sediment structures is a necessity for safety and environ-

Table 6. Runoff Curve Numbers for Selected Agricultural, Suburban, and Urban Land Use (Antecedent Moisture Condition II)

Land Use Description	Hydrologic Soil Group

mental protection. Flood routing and protective designs are required by several state and federal agencies. Design requirements are normally based on a certain frequency storm event, with storm frequency dependent on the size, how long the structure will be in existence, and the potential hazard if failure occurs.

Analysis of flood routing through a structure is normally accomplished by creating a hydrograph of the design storm to the inlet of the structure and a hydrograph of flow through the structure. The information required to develop the hydrograph of flow through the structure is stage storage information for the structure and discharge capacities of the outlet structures. Discharge capacities for structure with drop inlet and piped discharge are expressed by:

Fig. 18. Illustration of pipe flow control on a drop inlet spillway, outflow controlled.

Fig. 19. Inflow vs. outflow hydrograph.

$$Q = \frac{a (2gH)^{1/2}}{1 + K_e + K_b + K_c L^{1/2}}$$

where Q is cfs; a is the area of pipe in square feet; g is gravity, 32.2 ft per sec²; H is the head in feet above the horizontal section; K_e is ≈ 1.0 ; K_b is ≈ 0.5 ; K_c is the friction loss of pipe; and L is the length of pipe in feet

A typical configuration is shown in Fig. 18.

A resulting hydrograph for a typical structure is shown in Fig. 19. Sediment structures should be built in accordance with a preplan that considers: (1) required capacities, (2) stability and erosion protection for the embankment, (3) permeabilities and required compaction for embankment materials, and (4) conservative engineering design.

SUMMARY

Water management and pollution control are, and will continue to be, an increasingly demanding discipline in the surface mining industry. Innovation in the application of existing technology and the development of new technology will be a necessity for effective utilization of this country's surface minable resources. The broad technical background needed in the field makes it both challenging and rewarding.

6.7.2 Air Quality Management

CLIFFORD F. COLE
RICHARD L. KERCH

INTRODUCTION AND OVERVIEW

Owners and operators of surface mines are concerned about the air quality impact of their mines for two reasons. First, they want to be good neighbors and provide a healthy environment for both the mine employees and for the residents (often the employees and their families) who live near the mine. Second, state and federal regulations require that surface mines comply with stringent rules designed to limit pollutant emissions and to maintain ambient air quality at a level that will protect the public health and welfare. To achieve these goals, permit systems have been established by federal, state, and local regulatory agencies.

Permit systems require that the owners and operators of facilities that are significant sources of air pollutants, including surface mines, obtain permits before construction and operation of the facility can begin. The permit requirements differ from state to state, and federal permit rules frequently differ from state rules, but generally applicants are required to submit detailed design and engineering plans of their proposed facility, including the location of the proposed air pollution sources, the control systems to be installed, estimates of the air pollutant emission rates, and a demonstration that all applicable air quality standards and regulations will be met.

The regulatory agency then compares the predicted impacts against standards or guidelines, and if no harmful impact is anticipated, the agency will issue a permit. Air quality permits granted at surface mines frequently require that the owners or operators install pollution monitoring instruments in the vicinity of the mine to ensure that once operation begins pollutant concentration standards will not be exceeded.

A large surface mine may have to secure more than one air quality permit before mining can commence, and a lead time of as much as three years may be needed to gather ambient air quality data, prepare the permit application, and go through the review process before obtaining these permits. Clearly the acquisition of the necessary air quality permits is a major environmental priority in opening and operating a surface mine.

There are presently six major air pollutants whose emission rates and ambient concentrations are regulated by the federal government through the United States Environmental Protection Agency (USEPA). These so-called criteria pollutants differ in their characteristics, sources, and health effects:

1) Particulate matter is used to mean any dispersed matter, solid or liquid, in which the individual particles are larger than single molecules but smaller than about 500 μm (microns). Particles in this size range can remain suspended in the atmosphere from a few seconds to several months. Particulate matter is undifferentiated with respect to size, chemical or biological composition, optical or surface properties, motion, or source. Particulate matter is defined according to its size. Total suspended particulate matter (TSP) is the term given to particulate matter collected by a high volume sampler, which captures particles in the size range from 0.1 to about 100 μm in diameter. TSP has long been used as a

measure of airborne particulate matter. Particulate matter smaller than 10 μm in diameter is termed PM-10. EPA has adopted PM-10 as its measure of particulate matter, in light of evidence that only particles smaller than 10 μm are harmful to health and welfare. The use of TSP at the federal level will be phased out. However, many states and counties still use TSP as the sole measure of particulate matter.

At surface mines the sources of TSP are those areas or activities that cause dust to be entrained into the air—haul road traffic, ore or coal handling, wind erosion on exposed areas, overburden removal, etc.

2) Sulfur dioxide (SO_2) is one of the gaseous products of combustion emitted in the burning of sulfur-bearing fuels. It is also liberated during certain smelting operations and is produced in many industrial processes. Surface mines are a relatively minor source of SO_2 . The major source of SO_2 at surface mines is the combustion of diesel fuel in mining vehicles and other diesel-powered equipment. Ancillary facilities such as coal-cleaning plants or smelters can emit hundreds of times more SO_2 than the mines themselves.

3) Carbon monoxide (CO) is a colorless, odorless, poisonous gas caused by incomplete combustion of fuels. At surface mines, vehicle exhaust is the main source of CO , although the amount of CO emitted by mining is insignificant compared to the huge quantities generated by urban traffic.

4) The term nitrogen oxides (NO_x) is used to represent the composite atmospheric concentrations of nitric oxide (NO) and nitrogen dioxide (NO_2). The standard is expressed in terms of nitrogen dioxide. Both of these compounds are formed during the combustion of fossil fuels. NO_x emissions are often further classified as thermal NO_x (formed from nitrogen in the air reacting with oxygen at high temperatures) and fuel NO_x (resulting from the oxidation of nitrogen contained in the fuel). The primary sources of NO_x at a surface mine are internal combustion engines used in diesel and gasoline powered vehicles and mining equipment.

5) Lead (Pb) particles come primarily from the combustion of leaded gasoline and from lead smelters. Most surface mines are insignificant sources of lead.

6) Ozone (O_3) is a secondary pollutant that is caused by complicated reactions of hydrocarbons and nitrogen oxides in the presence of sunlight. Surface mines are an insignificant source of ozone.

In addition to the criteria pollutants listed previously, EPA also regulates other air pollutants, including:

Asbestos	Vinyl Chloride	Radon 222
Beryllium	Fluorides	Benzene
Mercury	Sulfuric Acid Mist	Radionuclides
Arsenic	Hydrogen Sulfide	Total Reduced Sulfur

Most of the permitting effort, the pollution control effort, and the air monitoring work at surface mines is devoted to particulate matter. Environmental protection personnel at surface mines will generally find that this is their greatest air quality concern.

On a nationwide basis, surface mines account for only a small fraction of the particulate matter emitted in the United States. Combining estimates of TSP emission rates in the US

Table 1. Annual TSP Emissions by Source Category*

Source	Emissions, thousand st	Emissions, % of total
Roads†	280,813	47.2

Metric equivalent: st \times 0.907 184 7 = t.

grouped by source categories (Evans and Cooper, 1980) one can see that mining emits 1.6% of all TSP, as shown in Table 1. The major sources of TSP are unpaved roads and agriculture, which together contribute over 90% of all particulate in the US. However, on a local basis in a remote area, a surface mine can be the dominant source of TSP.

The remainder of this section explains the major air pollution regulations with which a surface mine must comply and outlines the steps required to obtain air quality permits. Additionally, the air pollution monitoring phase is discussed, as are the sources and controls of air pollution at surface mines. Finally, methods of estimating the pollutant impact at a surface mine are presented, and the section concludes with a brief illustrative example.

AIR POLLUTION REGULATIONS

The authority to regulate sources of air pollutants, such as surface mines, is granted to many different governmental agencies through various forms of enabling legislation. At the federal level, the Clean Air Act (CAA) empowers the federal Environmental Protection Agency (EPA) to set national ambient air quality standards for all designated pollutants and to require that individual states submit a state implementation plan (SIP) outlining how the state will achieve and maintain these standards. The CAA was amended in 1977 to include the Prevention of Significant Deterioration (PSD) program, whose purpose is to prevent areas where air is already cleaner than the national air quality standards from becoming significantly more polluted, and the visibility protection program. Visibility protection and maintenance is a special permit consideration that must be addressed in situations where the proposed facilities' emissions might impair the visibility in or around any special federal land use areas known as Class I areas (e.g., national parks and wilderness areas). The techniques for assessing visibility impacts of surface mines on Class I areas have not yet been adopted by EPA. Although visibility impacts of surface mines on Class I areas have not routinely been considered in the permit review process, this analysis is expected to become more important in the future. It is also worth noting that the CAA provides additional protection to Class I areas for other air quality related values such as effects on flora and fauna. All sources of air pollution are subject to these federal regulations unless specifically exempted. While other federal agencies may also include restrictions or provisions that control air pollutants in their regulations, none are as broad or as all-inclusive as the EPA regulations.

At the state level, all 50 states have their own air quality control agencies with authority generally granted by state legislation. For the most part, the state rules parallel EPA regulations. The use of different measures of particulate matter (PM-10 and TSP) mentioned previously is a notable exception. Mines located in states that use TSP as an indicator of particulate matter may have to comply with both state TSP regulations as well as federal EPA PM-10 regulations. The authority for some federal programs, such as PSD, has been delegated to those state agencies that have desired to have their own programs.

Finally, local government may in some cases administer air quality regulations at the county, township, or city level. It is the responsibility of mine managers to be familiar with all applicable regulations and to ensure that the mine complies with them. Specific questions or information requests can be directed to EPA regional offices or to state air pollution control agencies. A summary of EPA regional offices appears in Table 2.

Ambient Standards

EPA has established two kinds of National Ambient Air Quality Standards (NAAQS): primary standards to protect the public health and secondary standards to protect the general welfare, including such things as injury to plants, animals, and materials. These national standards (Anon., 1979), shown in Table 3, are measures of pollutant concentration which must not be exceeded in the ambient air. Various averaging time intervals are specified for all of the pollutants to account for effects associated with exposure to both acute and long term concentrations. *Ambient air* has not been well defined. Practically, national ambient air quality standards (NAAQS) are most often enforced for areas outside of the company property if public access to the property is prevented (Hawkins, 1978). Mine Safety and Health Administration (MSHA) standards, where they exist, apply to areas inside mine property.

Whether or not a region is in compliance with the NAAQS is usually determined by measuring pollutant concentrations within that region. Monitoring networks measure concentrations over various time periods to determine whether an area is currently attaining ambient air standards (*attainment areas*), or whether a region's pollutant concentrations exceed the standards (*nonattainment areas*). A region can be an attainment area for one pollutant but a nonattainment area for another.

Because the EPA's PM-10 measure of particulate matter

* All short-term standards may not be exceeded more than one time per year, except for ozone and particulate matter which are treated in a different manner.

† Geometric mean for TSP; all other pollutants and averaging times are arithmetic means.

‡ Former NAAQS which may be retained by some states.

has only recently been adopted, there has not been sufficient time to measure PM-10 concentrations in order to determine which areas of the United States exceed particulate matter NAAQS. However, based on statistical analyses of existing TSP concentrations, and on limited PM-10 measurements, the EPA has identified 68 areas with at least a 95% probability of exceeding PM-10 NAAQS, and an additional 112 areas with greater than 20% probability of exceeding particulate matter NAAQS (Anon., 1987a). Many of these expected areas of exceedance are in the West and Southwest.

Individual states may have their own ambient air quality standards that must be met in addition to the national standards. These state standards are often equal to in numerical value, but occasionally more stringent than, the national ambient air quality standards. Some states may also have standards for additional pollutants not federally regulated.

State regulatory agencies ensure that new pollution sources, such as surface mines, will meet ambient air quality standards through a construction permit system. The permit process allows the agency to prohibit the construction and operation of new sources that might cause a violation of ambient air quality standards. When a proposed new source applies for a permit to construct, the agency requires as part of the permit review and approval process that the applicant demonstrate that the pollutant contribution from the proposed source, when numerically combined with preexisting pollutant concentrations in the air, will not exceed ambient air quality standards. This demonstration is most often made by computing the quantity of pollutants that will be emitted from a source, and then simulating the dispersion of these pollutants in the atmosphere by using an air quality model to calculate the total ambient air concentrations to which the public will be exposed in the vicinity of the source. The means of estimating air pollution impact from surface mines is discussed later in more detail.

Prevention of Significant Deterioration

The Prevention of Significant Deterioration (PSD) program, originally adopted by EPA in 1974, is designed to prevent attainment areas of the country from becoming significantly more polluted. The Clean Air Act was amended by Congress in 1977 to include the statutory authority and requirement for a PSD program. The PSD program applies only to attainment areas. Regulations implementing the PSD program were first adopted at the federal level and enforced by EPA. States have the option of promulgating their own PSD regulations, and if an individual state's regulations are approved by EPA, then the authority for the PSD program is delegated to that state. EPA retains the authority in states that choose not to have their own PSD program. Since most states' PSD rules mimic the federal regulations and since some states adopt the federal regulations by reference, the discussion in this section will focus on the federal PSD program.

The PSD program is made up of three major elements: an increment system for rationing the remaining clean air resources, a permitting system for implementing the program, and a control technology program requiring that the best available control technology (BACT) be installed and operated on all new sources subject to the regulations.

Under the PSD program (Anon., 1980a), the attainment areas of the US are divided into three categories or classes. Class I areas are those where the least amount of future air quality deterioration is to be allowed (up to 7% of the standard). These areas include many national parks, international parks, Wilderness Areas and national memorial parks. Class II areas, which at present include all of the remainder of the US, are allowed additional air quality deterioration (up to approximately 25% of the standard). Class III areas would be allowed still greater levels of pollution. There are no Class III areas, and none are anticipated since a rather complicated redesignation process must be followed to reclassify a Class II area to Class III status. The amount of increased pollution in Class I, II, or III areas is limited by the PSD program to maximum allowable increases, known as increments. In no case can the air quality be allowed to deteriorate to the point that the NAAQS are violated. The numerical values of these increments are shown in Table 4 for SO₂, TSP, and NO₂. These three pollutants are the only ones presently regulated under the federal PSD program, although there are statutory provisions to regulate the other criteria pollutants. Notice that the particulate matter PSD increment in Table 4 is expressed in terms of TSP concentration, whereas the National Ambient Air Quality Standards (Table 3) use PM-10 as a measure of particulate matter. This disparity results from the recent adoption of PM-10 as a measure of particulate matter. EPA intends to establish PM-10 increments in the future. Until that time, however, two different measures of particulate matter concentration persist in air quality regulations.

The allowable increments define the maximum allowable air quality deterioration over and above a baseline level. The baseline level is generally the prevailing ambient concentration on the day that the first pollutant source with significant pollutant emissions applies for a PSD permit. This day is called the baseline date. Some states, however, have adopted fixed baseline dates. The concepts of baseline date, baseline concentration, and baseline area are very poorly defined and often confusing. States have been given the authority to define these important terms; as such, no universal definition exists. All major sources of SO₂, TSP, and NO₂ which apply for PSD permits after the baseline date are considered consumers of PSD increment. Once a source consumes part of the increment, that portion is unavailable to other sources. No new source will be granted a PSD permit if its ambient concentration contributions exceed the remaining increment. There are some portions of the nation where the available PSD increment has already been totally consumed, and no new

Table 4. PSD Increments ($\mu\text{g}/\text{m}^3$)

20.	Chemical process plants
21.	Fossil-fuel boilers (or combination thereof) totalling more than 73 MW (250 million Btu/hr) heat input
22.	Petroleum storage and transfer units with a total storage capacity exceeding 300,000 bbl
23.	Taconite ore processing plants
24.	Glass fiber processing plants
25.	Charcoal production plants
26.	Fossil fuel-fired steam electric plants of more than 73 MW (250 million Btu/hr) heat input
27.	Any other stationary source category which, as of Aug. 7, 1980, is being regulated under Section 111 or 112 of the Act.

growth will be allowed without a suitable offset and perhaps not even then.

The PSD program is administered through a permitting process at the federal level, or if the state has been granted authority, at the state level. Not all air pollution sources are subject to PSD. Only sources above a certain size threshold (*major sources*) or source modifications above a certain size threshold (*major modifications*) are required to obtain PSD permits. For PSD purposes, a *major source* is one that has the potential to emit over 226 t (250 st) per year of any criteria pollutant or a source belonging to a list of 27 specific source types (shown in Table 5) that has the potential to emit over 90 t (100 st) per year of a criteria pollutant. Potential to emit means the maximum capacity of a stationary source to emit a pollutant under its physical and operational design. Any limitation on the capacity of the source to emit, including air pollution control equipment or restrictions of hours of operation or on the type or amount of material combusted, stored, or processed can be treated as part of its design if the limitation or effect it would have on emissions is generally enforceable, i.e., through the operating permit.

Special provisions apply to fugitive dust (the windblown particulate matter that could not pass through a stack or a vent) under PSD. These provisions are extremely important to surface mine operators since fugitive dust accounts for the vast majority of particulate matter emissions at surface mines. EPA provisions allow a fugitive dust source to escape PSD review if two conditions are met: (1) the source is major only because of the magnitude of fugitive emissions and (2) the source is not included in the list of sources in Table 5. The reason for this so-called fugitive dust exemption is that

there is ample evidence that natural dust with particles in the size range emitted at surface mines is not detrimental to health.

However, once the source triggers PSD review, e.g., the source is major for another pollutant, then fugitive dust is always included in calculating PSD increment consumption for particulate matter. It is also possible that a nonmajor stationary source with fugitive dust emissions in excess of the applicable PSD threshold may get entangled in increment consumption indirectly through EPA requirement on the states to *track* increment consumption for both major and nonmajor sources.

Legal challenges have been made to the present fugitive dust exemption by environmental groups. In particular, EPA has proposed to add surface coal mines to the list of 27 sources which would result in the loss of the fugitive dust exemption for that source category. There are many indications that if EPA regulations were changed to force surface mines to undergo full PSD review, many mines could not be permitted at an economic designed capacity because the magnitude of their fugitive dust emissions would exceed the available TSP increment near the mine (Anon., 1979b; Cabe, Hooper, and Schmidt, 1979; and Anon., 1982). The final resolution of this fugitive dust controversy may have a great impact on the surface mining industry.

There is one other important requirement under PSD which all new sources must meet—each source must apply Best Available Control Technology (BACT). Whether a piece of control equipment or a control method qualifies as BACT is to be judged on a case-by-case basis, taking into account energy, environmental, and economic impacts and other costs (Anon., 1978b). While the use of water spray to

control dust on a haul road, for example, may qualify as BACT in one instance, elsewhere chemical dust suppressants may be required. Control technology used in similar installations frequently influences BACT determinations and these previous applications of BACT have been compiled in a reference book (Anon., 1985a).

If a source, such as a surface mine, does have to apply for a PSD permit, EPA requires that four major analyses or demonstrations be made before a permit can be granted:

1) The applicant must demonstrate that the source will not cause exceedances of the allowable PSD increments and will not exceed ambient air quality standards. These demonstrations must be made by predicting the air quality impact of new sources with EPA-approved dispersion models.

2) The applicant must demonstrate that the new source will apply BACT.

3) The applicant must analyze any air quality impacts projected for the area as a result of growth associated with the proposed source.

4) Using air pollution sampling instruments, the applicant may have to monitor the air quality concentrations in the vicinity of the source both before and after construction.

Nonattainment Regulations

It is not often that a proposed surface mine would be located in or near to a nonattainment area but the situation has occurred. In nonattainment areas, where pollutant standards are not being met, EPA is faced with addressing conflicting goals—allowing new industrial growth to add to the pollution levels already in violation of the law, while at the same time improving the quality of the air to meet ambient standards (Raffle, 1979). EPA has seemingly resolved the conflict by promulgating its *Offset Policy*, wherein new pollutant sources are allowed to locate in a nonattainment area only if they can reduce pollutant emissions elsewhere in the area so as to more than offset their emission rate increases. The net effect should be an overall improvement in air quality.

The nonattainment regulations encompass four separate provisions, each of which must be met before a source in a nonattainment area will be allowed to construct (Anon., 1980). First, the new source must agree to limit its pollutant emissions to the Lowest Achievable Emission Rate (LAER), meaning that pollution control equipment and operating practices will be such that pollutant emissions will be as low as those from any similar existing source. In practice, LAER determinations are often set by precedent established in pre-

vious permitting efforts. The second provision is that the applicant must certify that other pollutant sources in the state owned or operated by the applicant are complying with all applicable regulations. Third, an emissions offset must be provided for the same pollutant that the new source will emit in an amount at least as great as the proposed increase. Fourth, the effect of the offset in combination with the proposed increase must result in a net benefit in air quality in the affected area. This last provision essentially means that the offset must occur reasonably near the intended new pollutant source location—a decrease in TSP emissions 64 km (40 miles) from a proposed new mining operation, for example, would not achieve the desired net benefit in air quality and probably would not be approvable as an offset.

EPA did not intend that every pollutant source, regardless of size, abide by its nonattainment regulations. Clearly, to regulate sources which emit only insignificant quantities of pollutants would do little to improve air quality and would impose a needless burden on the applicant and EPA alike. These regulations are therefore limited to *major* new sources or *major modifications* to existing major sources. A major source is defined as one which emits, or has the potential to emit, 90 t (100 st) per year of any nonattainment pollutant. A major modification is a change in a major source that results in a net emissions increase that equals or exceeds the rates shown in Table 6.

Emissions Regulations

The next type of air pollution regulations to which surface mines are subject is emission limitations. Emission limitation regulations directly specify the maximum quantity of pollutants that a source may legally emit within a given time. Emission regulations are conceptually different than ambient air regulations or PSD, each of which seek to control the resulting ambient air concentrations downwind of a pollutant source, and only indirectly control the pollutant emission rate of that source.

Emission regulations take many different forms. At the federal level, New Source Performance Standards (NSPS) restrict the emissions of pollutants from over 50 different source types that EPA feels have a significant impact on air quality. Although surface mines by themselves do not appear on this list, there are new source performance standards for some facilities commonly found on mine property, e.g., coal cleaning plants and petroleum storage vessels. Most states have adopted the federal NSPS and made them a part of their state laws.

Table 6. Significant Net Emissions Increase Rates

Pollutant	Emission Rate, st per year	de minimis concentration, $\mu\text{g}/\text{m}^3$
Particulate matter		
TSP	25	10 (24-hr)
PM-10	15	10 (24-hr)
Sulfur dioxide	40	13 (24-hr)
Nitrogen dioxide	40	14 (annual)
Carbon monoxide	100	575 (8-hr)
Ozone (VOCs)	40*	not applicable
Lead	0.6	0.1 (3 month)

* A net emissions increase for ozone is considered significant if a source emits 36.3 t/a (40 stpy) or more of volatile organic compounds (VOCs).

† Ambient concentration and associated averaging time in parentheses.

Another kind of emission limitation that may be applicable is the process weight rate regulation, which restricts the amount of particulate matter from industrial processes as a function of the material throughput. These regulations would not apply to a surface mine per se, but they would apply to specific processes such as coal or ore crushing. Almost all states have their own process weight regulations. As an example, the maximum particulate emission rate from a new process source in Wyoming (Anon., 1982c) that has a throughput rate of less than 27 t (30 st) per hour is given by

$$E = 3.59 P^{0.62}$$

where E is the allowable emission rate in pounds of particulate per hour and P is the process weight rate (throughput) in tons per hour.

A third type of emission regulation is the fugitive dust regulation, commonly adopted by state regulatory agencies. This regulation specifies the level of control that is expected to be used at fugitive dust sources and may require such controls as water spraying on dirt roads, prompt revegetation of stripped areas, covering of haul trucks using public roads, etc. These regulations for fugitive dust are generally non-quantitative.

Other kinds of emission regulations sometimes encountered include volumetric in-stack gas concentration limits; mass per unit time regulations which limit emissions to a specific number of pounds per hour; and mass per unit of activity regulations.

AIR POLLUTION MONITORING

Air quality monitoring networks consist of a collection of instruments that measure air pollutant concentrations and meteorological parameters in the vicinity of a surface mine. Before construction of a mine begins, the regulatory agency often requires that between four months and one year of pollutant concentration data be gathered. The purpose of this effort is to determine what the existing background concentrations are so that when the additional pollution concentrations expected from the mine are calculated, they can be added to the existing background to check whether the mine will comply with air quality standards. The rules that dictate which pollutants must be sampled are complex (Anon., 1978a), but frequently a mine will be required to monitor only for particulate matter. Pollution sources that are large emitters of gaseous pollutants and that may be located adjacent to surface mines (smelters, coal-fired power plants, etc.) are often required to monitor SO_2 , NO_x , CO , and ozone prior to construction.

The requirement to monitor background pollutant concentrations may be waived by regulatory agencies under certain circumstances. If a source's pollutant emission rates are expected to be less than the significant levels shown in Table 6, or if existing background concentrations or a source's expected concentration contributions are less than so called *de minimis* levels shown in Table 6, then the source may be granted a monitoring exemption. In all cases, mine management should check with the responsible regulatory agency before taking advantage of monitoring exemptions.

In areas distant from conventional weather stations, it may be necessary or desirable to gather meteorological data prior to construction of a surface mine. The parameters most often measured are wind speed, wind direction, standard deviation of wind direction, and temperature. Occasionally, relative humidity or dew point, solar insolation, evaporation

rate, and precipitation are also measured. Some of these data will later be used as input to computerized pollutant dispersion models that predict the air quality impact of a proposed mine. The remaining data may be useful in planning reclamation.

Particulate Matter Monitoring

The most common ambient air quality monitoring device in the mining industry is the high volume sampler. Total suspended particulate (TSP) concentrations are measured with a hi-vol. The hi-vol consists of a filter holder and a blower motor housed in a shelter. The electric blower, identical to the kind often used in vacuum cleaners, draws air through a filter which captures particulate matter. By weighing the filter before and after exposing it, the mass of particulate matter can be determined. Additionally, the volume of air that passes through the filter is measured, so that the ratio of particulate mass to total air volume yields the average TSP concentration. The hi-vol is usually run for 24 hr at a time so that the resulting concentration is directly comparable to 24-hr ambient air quality standards. A hi-vol and shelter are shown in Fig. 1.

The accuracy with which a TSP concentration can be determined by the hi-vol method depends upon how accurately the hi-vol filter can be weighed and the volume flow measured. A typical hi-vol with flow controller costs about \$3000 (1988 dollars). With the recent adoption of PM-10 as a measure of particulate matter concentration, special samplers that collect only particulate matter smaller than $10 \mu\text{m}$ are being used. The PM-10 samplers are very much like hi-vols, but with carefully designed inlets that admit only particles with mass median diameters less than 10 microns. These particles are collected on filters and subsequently weighed to compute concentration in the same way as with the hi-vol sampler. A PM-10 sampler costs about \$5,000. The frequency with which PM-10 must be sampled, and the means of determining compliance with the PM-10 standards, are somewhat more complicated than for TSP.

Operation and maintenance of particulate matter samples, including the filter weighing activity and particulate concentration computations, can be performed by mine personnel. Otherwise, the filters can be sent to commercial laboratories, some of which offer complete *turnkey* services including filter analysis, data reporting, instrument calibration, and maintenance.

Fig. 1. Hi-vol sampler (courtesy of Flatiron Cos.; photograph by A. Tuggle).

The ratio of PM-10 to TSP concentrations has been measured at several places including mining and non-mining areas. Based upon these measurements, it is estimated that this ratio varies from about 25% to 60%.

Gaseous Pollutant Monitoring

In rare instances, such as when a surface mine has a thermal dryer or is to be located adjacent to a smelter, mine management may be required to sample gaseous pollutants like SO_2 , NO_x , CO, or ozone. Instruments that measure these pollutants are much more costly, and require more attention than do particulate monitors. Usually gaseous pollutant monitors are housed in temperature-controlled sheds or trailers. Ambient air is drawn into the shed through glass manifolds and is introduced to the instruments which sense pollutant concentrations as low as a few parts per trillion. Real-time measures of pollutant concentrations detected by these instruments can be recorded on strip chart recorders, or can be digitized and recorded on magnetic tape cassettes, for subsequent analysis. Unlike the particulate samplers intermittent operation, gaseous pollutant instruments are run continuously. The capital cost of a complete gaseous pollutant sampling trailer with SO_2 , NO_x , and ozone instruments and recorders can be as high as \$50,000. The operating costs of such a sampling station, including routine maintenance and data reduction, would be roughly \$30,000 per year.

Meteorological Monitoring

Before a surface mine is opened it may be necessary to collect meteorological data for subsequent use in pollution dispersion modeling studies. Meteorological measurements such as wind speed, wind direction, temperature, and precipitation, can be made continuously with self-contained, unmanned sampling stations, like the ones shown in Fig. 2.

These stations record data onto paper strip charts or magnetic cassettes. Meteorological data collection stations require a source of electrical power, which sometimes can be provided by solar cell and battery units, or by portable gas generators, where electrical utility service is unavailable. The capital cost for a sampling station with cassette recorders similar to the one shown in Fig. 2 is roughly \$10,000, and the operating costs, including maintenance and data reduction, may be about \$5000 per year.

SOURCES AND CONTROL OF AIR POLLUTION

Recognizing the sources of air pollution at a surface mine and knowing how to control them is at the heart of good air quality management. All actions that ultimately limit the emission or entrainment of pollutants into the air have a direct consequence on pollutant concentrations at the mine site, and if a mine exceeds an ambient air pollution standard, only reduction or cessation of pollutant emissions will help meet that standard.

Because particulate matter emission rates far exceed the emission rates of other pollutants at surface mines, the activities and sources that emit particulate matter deserve special attention. Particulate matter sources can be divided into two categories: mining activities that generate windblown dust (fugitive dust), and materials handling and processing activities whose particulate matter emissions are, or could be, emitted through a vent or a stack (nonfugitive dust).

The distinction between these two types of particulate matter sources is more than academic. As discussed previously, the magnitude of a mine's nonfugitive particulate matter emissions determines whether the mine is subject to PSD regulations. Furthermore, the way in which dust is controlled from these two source types differs. Fugitive dust source

Fig. 2. Remote meteorological sampling stations (courtesy of Flatiron Cos.).

emissions can be minimized somewhat by water spraying, reclamation, etc., but because of the exposed nature of these sources, it is impossible to totally eliminate fugitive dust emissions. Dust from enclosed, nonfugitive emission sources, on the other hand, can be vented to filters and other air cleaning devices that remove as much of the particulate matter as desired.

The remainder of this section discusses the various fugitive dust mining sources, the nonfugitive sources characteristic of materials handling and processing, and gaseous pollutant sources. In each case pollution control devices and practices are described.

Fugitive Dust Sources

Fugitive dust is generated by mining activities that disturb topsoil, overburden, or ore, causing dust to be emitted into the air. Fugitive dust that remains airborne is measured by the samplers discussed previously. Sources of fugitive dust at surface mines can be conveniently discussed in the same sequence that mining occurs (Anon., 1982b):

Construction: Construction of a mine involves clearing vegetation, site grading, building roads, and erecting permanent facilities. Operation of graders, dozers, and other heavy equipment "kicks up" fugitive dust into the air. These dust emissions can be controlled by restricting the area of disturbance and by spraying water on disturbed areas to prevent dusty conditions.

Topsoil Stripping: Scrapers used to strip topsoil can cause considerable dust emissions. Fugitive dust emissions caused

by stripping can be reduced by watering, by restricting the speed of the scrapers, by minimizing the length of time that the stripped areas are exposed to wind erosion, and by limiting the total area stripped.

Drilling: Blasthole drilling, whether in overburden, ore bodies, or coal, is a source of fugitive dust. Careful planning can minimize the number of holes drilled, thereby saving money and reducing dust emissions. Additionally, dust from drilling can be controlled by water injection systems or by shielding the drilling area to prevent dust from being carried by the wind. When air circulation is used, dust at the top of the drill hole can be collected by a shroud or skirt and vented through a mechanical dust collector on the drilling rig.

Blasting: Blasting is a spectacular, but surprisingly insignificant, source of fugitive dust. Because blasting occurs infrequently, it does not generate as much dust over a period of time as more continuous fugitive dust sources such as topsoil stripping. Dust from blasting can be minimized by careful stemming and by avoidance of overshooting.

Overburden, Ore, and Coal Removal: Although several different pieces of equipment are used for material removal—draglines, shovels, scrapers, wheel excavators, dozers, and front-end loaders—operation of each is a significant source of fugitive dust at surface mines. In surface mining the fugitive dust is generated by shovels and draglines first when material is scooped into the dipper or bucket, and again when the material is dropped into the spoil site. Similarly, in open pit mining dust is created in scooping and dropping material onto trucks. In either case, dust can be controlled by minimizing the drop distance that material falls onto spoil piles or trucks. When scrapers and dozers are used, little can be done to control dust emissions other than to restrict scraper speed, minimize dozer push distances, or in extreme instances curtail operation during high winds.

Material Hauling: For most surface mines, haul truck traffic over unpaved roads is the predominant source of fugitive dust. Dust is picked up by the action of the trucks' tires, and then drawn into the aerodynamic wake behind the truck. The most commonly observed source of fugitive dust at surface mines is the plume of dust behind a large, fast-moving haul truck. The continuous nature of this source explains why haul truck traffic accounts for as much as 75% of all particulate emissions at some western mines. The magnitude of dust emissions from haul trucks increases with truck speed, truck weight, the physical size of the vehicle, the number of tires per truck, the silt content of the unpaved

road, and of course, the total number of truck miles traveled. Haul road dust can be controlled most cost effectively by limiting the haul road length and minimizing the number of round trips that each truck must make. From the standpoint of dust control, the use of larger payload haul trucks is preferable to the use of smaller trucks which must make more circuits. Another means of limiting haul road fugitive dust emissions is to restrict truck speed. It should be noted that parameters such as haul length, truck speed, payload, and other haul cycle factors are generally chosen to optimize productivity rather than to minimize dust (Bishop, 1968).

A more direct means of reducing haul truck fugitive dust is to treat the road surface to minimize dust. This can be accomplished by routine watering, by removal of loose debris on roadways, and by application of dust suppressing chemicals. Watering is the most commonly used dust control and, of course, its effectiveness depends on the frequency of water spraying and on the climate at the mine. The correct application rate is one that eliminates visible dust plumes behind haul trucks but does not make the road muddy. Routine spraying requires available water and the appropriate equipment and labor. Haul roads cannot always be watered in freezing weather.

The application of chemicals to a haul road inhibits dust by forming a hard, relatively smooth surface. Most chemical surface treatments require special preparation of the road before application, and while chemical dust suppression is initially costly, savings may be realized by less frequent need to apply water. Table 7 compares features of several dust suppression chemicals.

Stockpiles: Topsoil, overburden, ore, and coal are sometimes stored in exposed stockpiles before being replaced or shipped off site. Stockpiles are sources of fugitive dust when material is added to or removed from the pile and when wind erosion blows material from the pile. Minimizing the size and number of stockpiles reduces the wind erosion dust, as does vegetation or water sprays. Windbreaks can be built on the predominant upwind side of the stockpile to reduce emissions.

Fugitive dust from coal stockpiles is often avoided by building facilities that enclose the load-in, reclaim, or storage areas altogether. A shroud attached to a conveyor stacker, for example, isolates coal load-in from wind action. Similarly, an underground reclaim conveyor eliminates windblown fugitive dust. The ultimate control is to use a fully enclosed coal storage barn or silo which obviates the exposed stockpile altogether.

Table 7. Costs for Chemical Road Dust Suppressants

Palliative	Costs per Gallon,* \$	Application Rate, gal per sq yd	Dilution	Cost for 2000 sq yd Section, \$	Maintenance Frequency	Maintenance Costs, Annual, \$
Petroleum resin	1.22	1	1:4	496	every 6 wks. (1:9 dil.)	199 per occur. 725 per year
Emulsified asphalt	2.95	2.25	None	13,275	none	none
Calcium lignosulfonate†	0.184	1	1:1	418	every 6 wks. (1:3 dil.)	209 per occur. 1811 per year
Magnesium chloride	0.425	0.5	None	579	every 6 mos. (1:1 dil.)	289 per occur. 578 per year

Source: Larson, 1981.

* Does not include freight cost to mine.

† Application rate and costs are assumed.

Metric equivalents: gal \times 3,785 412 = L; sq yd \times 0.836 127 4 = m².

Wind Erosion: Wind erosion of unvegetated or exposed areas can be a source of fugitive dust. The best control measure is to minimize the area exposed to wind erosion and to limit the time over which areas are exposed. Prompt revegetation restricts wind erosion dust.

Nonfugitive Dust Sources

Nonfugitive dust sources are those whose particulate emissions can be contained by an enclosure of some sort and exhausted through a vent or stack. The reason for enclosing these dust sources is to prevent windblown dust emissions and to allow dust to be routed to air cleaning devices. Nonfugitive dust sources include most materials handling and processing facilities at surface mines, such as crushers and rail car loading stations. These nonfugitive dust sources are often termed *point sources* because their emissions come from a single, identifiable point such as a stack, in contrast to emissions from a fugitive dust source which emanate from a wide area.

Point source emissions are amenable to control by air-cleaning devices. Air-cleaning devices used to remove particulate matter from facilities at surface mines are generally of three distinct types—inertial separators, wet control devices, or fabric filters (Danielson, 1973). An inertial separator uses an abrupt change in the flow direction of a gas stream to separate out heavier particulate matter. Cyclone separators and baffles are common inertial separators which are rugged, simple, and inexpensive, but they are only capable of removing larger particulate matter. Wet collection devices, such as water sprays or scrubbers, introduce a water spray into a gas stream to impinge smaller particulate matter. Disposal of the waste water is sometimes a problem, and in freezing weather the water spray must be shut off or an anti-freezing solution must be used. Fabric filters (baghouses), the third type of control device, force air through a cloth filter to provide a very efficient, but expensive, means of removing particulate matter as small as $1.0\ \mu\text{m}$ in diameter. Facilities at surface mines may use any one or a combination of these three devices.

There are a number of nonfugitive dust sources at surface mines:

Material Dumping: Ore and coal are dumped into a hopper after being transported from the surface mine and this activity creates dust emissions. These emissions can be controlled by minimizing the distance that the material falls, and by spraying the hopper openings and vents with water to intercept escaping dust. More sophisticated, and expensive, dust control results by enclosing the dump area and by exhausting the displaced air through a baghouse. When the material dumping occurs intermittently, as when haul trucks dump into a crusher, the spray or baghouse can be actuated automatically when the dumping occurs.

Crushing and Screening: Depending upon the material being processed, there can be significant dust emissions at primary and secondary crushers, grizzlies, and screens. Crushing is an especially dusty operation because it creates and exposes new material faces which are the sources of fines. Enclosing the crushers and screens is a first step towards controlling this dust, and water sprays and negative pressure dust pickups exhausted through a cyclone or baghouse can be utilized to further reduce dust emissions.

Conveyors and Transfers: Belt conveyors are almost always preceded by a crushing operation, so that unless fines have been removed or the material is wet, conveyors and transfers can be very dirty. Minimizing the fall distance from the feeder to the conveyor belt reduces dust emissions at

transfers, as does the use of water sprays or negative pressure dust pickups vented to a baghouse.

Enclosing the conveyor on the top and sides prevents wind from blowing dust into the air. Total enclosure of the conveyor further reduces emissions, but interferes with maintenance. For very dusty materials with dry, powdery fines, it may be necessary to reduce belt speeds.

Storage: Fully enclosed silos or storage barns avoid the windblown dust problems associated with stockpiles, but there is still a need to ventilate these enclosures and to control dust displaced during loading. Forced air ventilation will often exhaust through a cyclone or baghouse.

Rail Car Loading: Dust is generated when product or ore is transferred into railcars. If the material is loaded by conveyor then a telescoping chute can be used to minimize the fall distance to the car and a fabric shroud can protect the material from wind. Water sprays are somewhat effective in controlling dust, but they increase the load mass and may cause freezing. Some coals are sprayed with oil which inhibits dust and also increases the heating value of the product.

Gaseous Pollutant Sources

Although the magnitude of gaseous pollutant emissions are dwarfed by dust emissions at most surface mines, gaseous emissions occasionally can be a problem. There are four sources of gaseous pollutants—sulfur dioxide, carbon monoxide, oxides of nitrogen, and hydrocarbons—at surface mines:

Vehicle Exhaust: Diesel and gasoline exhaust contains all four combustion product pollutants (TSP, SO_2 , NO_x and CO) to some degree. The best way to control these pollutant emissions is to maintain the engine with regular service.

Industrial Boilers: Some surface mines employ small industrial boilers to provide steam for space heating, or less often, for electrical generation. These boilers can be major sources of nitrogen oxides and hydrocarbons. If high sulfur coal is burned, then sulfur dioxide may be emitted in large quantities. The pollution control measures that a mine manager has at his disposal include good operating practice and routine maintenance.

Thermal Drying: Thermal drying of coal or concentrate at a mine or mill can be a significant source of gaseous pollutant emissions. Scrubbing systems can be used to minimize sulfur dioxide emissions when coal is burned to produce heat. If natural gas is used as a fuel for thermal drying, SO_2 emissions will be negligible. NO_x and CO emissions must also be addressed.

Storage Tanks: Fuel storage tanks can be sources of hydrocarbon emissions as air is displaced during tank filling, and as natural heating and cooling of the tanks expels air.

QUANTIFYING AIR POLLUTANT EMISSIONS

Once the sources of air pollutants at a surface mine have been identified, the magnitude of the pollutant emissions from these sources can be estimated. The quantification, called an emissions inventory, serves three purposes. First, as explained earlier, it determines whether certain air pollution regulations are applicable to a particular mine or mine modification. Second, the emissions inventory is frequently required in air quality permit applications, and if a computer model simulation of a mine's impact on the surrounding air quality is needed, then the emissions inventory is used as an input to the model. Third, the emissions inventory provides the mine manager with a relative estimate of the magnitude of pollutant sources so that control efforts can be applied in a cost effective manner.

The fugitive emissions from a mining activity are most frequently determined from an emission factor, i.e., an equation that relates pollutant emission rates to mining or climatological parameters. For example, the particulate emissions caused by unloading run-of-mine coal into a crusher may be a function of the moisture content of the coal, the average wind speed at the hopper, and the number of tons of coal unloaded. As the coal surface moisture increases, the dust emissions would decrease; as the wind speed or the coal throughput increase, the emissions would increase. Additionally, the effects of various pollution control efforts can be taken into account in the equations. Emission factor equations reduce the emissions inventory task to a simple paper and pencil exercise, which can be initiated as soon as a detailed mine plan is available.

Emission factors for fugitive dust sources are derived from empirical tests made at operating mines. In these tests ambient air pollutant concentrations are measured downwind of a mining activity, and then using an air quality dispersion model or other techniques, the emission rate needed to account for the observed concentrations is determined. If the field tests are conducted over a comprehensive range of climatological and operating conditions, then the emission rate can be statistically related to these conditions. Because of the inherent errors in field measurements, the wide variation in pollutant emission rates and the large number of possible explanatory variables, fugitive dust emission factors are not very accurate. Even rigorously conducted field experiments yield emission factors that are accurate only to within a factor of three (Axetell and Cowherd, 1981); typical emission factors may be significantly less accurate (Cole, et al., 1985). Despite this inaccuracy, emission factors are widely used to estimate pollutant emission rates because there is at present no better quantitative method.

Emission Factor Parameters

Emission factor equations include a wide array of parameters upon which pollutant emissions depend. Some of the most common parameters, or variables, are described below (Curreri and Heinold, 1982):

Silt Content: Silt content reflects the amount of fines in an overburden, topsoil, ore, or mineral product, and determines how dusty the handling of these materials will be. Silt content is expressed in percent and is equal to the mass fraction of material that passes through a 75- μm (200-mesh) screen. Note that this definition of silt commonly used in emission factors may differ from that used in other disciplines.

Moisture Content: This is the mass fraction of water, expressed in percent, of a material. The higher the moisture content, the lower the particulate emissions.

Drop Height: In some instances dust emissions are proportional to the distance that ore or product drops while being transferred or loaded.

Vehicle Miles Traveled: Dust emissions from roads are generally proportional to the total vehicle miles traveled (VMT) on the road.

Wind Speed: Fugitive dust emissions frequently depend upon the average surface wind speed at a mine. As wind speeds increase, the aerodynamic drag force on particles also increases, thereby entraining more dust into the air.

Wet Days: Many emission factors use a term called *number of wet days*, which is merely the average number of days per year that precipitation exceeds 0.254 mm (0.01 in.) at a particular location. The number of wet days per year affects the surface moisture at a mine, which in turn affects the

emission rate of windblown dust. Fig. 3 shows the mean number of wet days per year for the United States.

Precipitation-Evaporation Index: The Thornthwaite precipitation-evaporation index (*P-E index*) is a more sophisticated measure of surface moisture. Values of the P-E index are displayed in Fig. 4.

Climate Factor: A climate factor, equal to

$$\frac{0.345u^3}{(P-E)^2}$$

where u is the wind speed in miles per hour and P-E is the Thornthwaite precipitation-evaporation index as used in computing wind erosion dust emissions. The climate factor can be computed directly if u and P-E are known, or it can be determined from a handbook (Jutze and Axetell, 1974).

Emission Factors and Control Efficiencies

There are many different emission factors for computing fugitive and nonfugitive pollutant emission rates at surface mines. The key to selecting the best factor to predict emissions from a particular mining activity is to choose one that best represents prevailing operational and meteorological conditions. Factors to predict coal dust emissions from crushing at a mine in Montana, for example, ideally would be ones derived from western coal mine data, where climatology and coal characteristics would be similar. Since selection of specific emission factors is a very important part of preparing an emissions inventory, state or federal regulatory agencies should be consulted. The most widely used, and commonly accepted, emission factor handbook is EPA's *Compilation of Air Pollutant Emission Factors* (Anon., 1985).

Tables 8 through 13 present a number of emission factors often used to prepare pollutant emission inventories. Many of the factors pertain to surface coal mines because much of the measurement work has focused on coal mining. The emission factors are grouped by mining activity.

Material Removal: Table 8 summarizes emission factors used to predict particulate emissions caused by material removal and load-in to haul trucks. Emissions differ according to the equipment used and the material handled.

Drilling and Blasting: Table 9 shows emission factors that apply to drilling and blasting operations. Particulate emissions are expressed in pounds per drill hole or pounds per blast.

Dumping, Crushing, and Conveying: In Table 10 factors are shown that predict particulate emissions from dumping, crushing, and conveying. Emissions caused by dumping into a hopper can be reduced by 50% by using water sprays, and by 95% by controlling emissions with a negative pressure enclosure exhausted to a baghouse (Anon., 1979a). Similarly, use of a fabric filter baghouse at conveyor transfer points and crushers reduces emissions predicted by the equations by 99%.

Stockpiles: Particulate emission factors associated with stockpiles are summarized in Table 11. Fugitive dust emissions are caused by load-in and load-out operations and by natural wind erosion. Active stockpiles which are disturbed by equipment emit more dust than inactive stockpiles in which the material forms a crust. Emissions during load-in operations can be reduced by 50% by water spray, or by as much as 90% by applying chemical dust suppressants at the load-in point. Wind erosion dust losses can be reduced by 90% on inactive stockpiles by chemical stabilization or by revegetation. The ultimate control efficiency at stockpiles is achieved by enclosing them, an effort which may be prohibitively expensive.

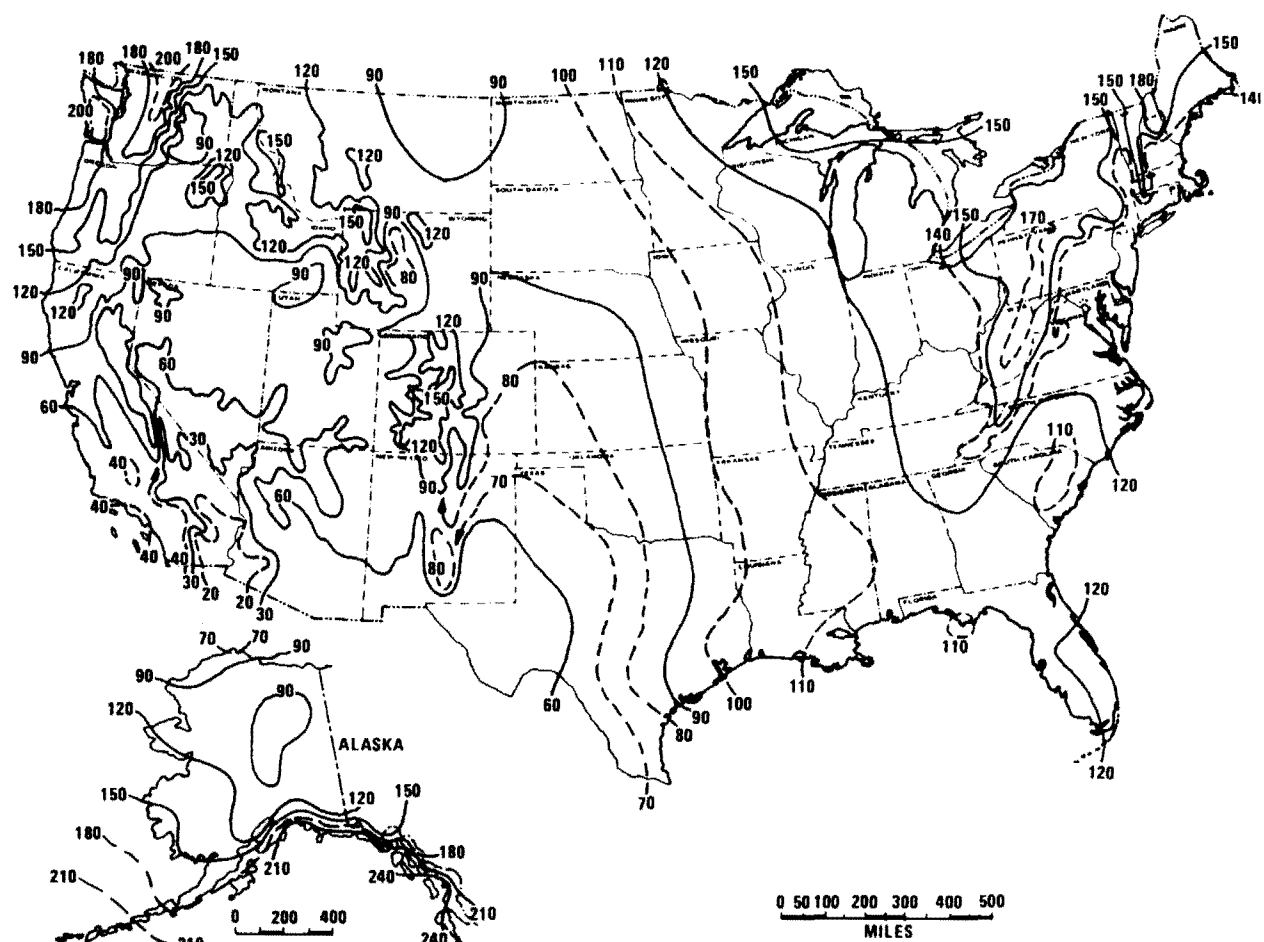

Fig. 3. Mean number of wet days per year (Anon., 1985).

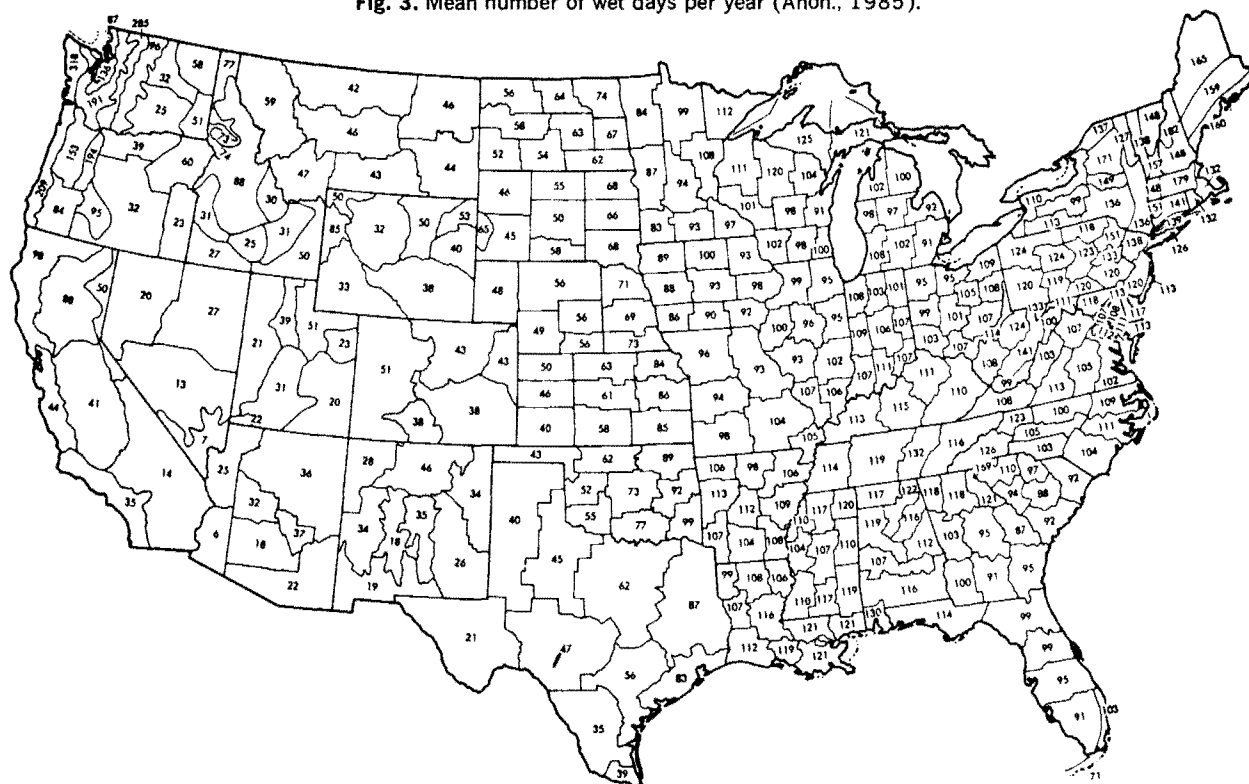

Fig. 4. Values of Thornthwaite's precipitation-evaporation index (Anon., 1985).

Table 8. Particulate (TSP) Emission Factors for Material Removal and Loading

Activity	Factor	Reference	Comments
Topsoil removal	16 lb per scraper hr	Anon., 1976a	
	0.38 lb per cu yd	Anon., 1978	Scraping and dumping
	$(2.7 \times 10^{-5}) S^{1.3} W^{2.4}$ lb per VMT		Scraper Travel
Overburden removal	0.037 lb per st	Anon., 1979a	truck and shovel
	16 lb per scraper hr	Anon., 1979a	scraper
	0.053 lb per cu yd	Anon., 1978	Wyoming dragline
	0.0021 $d^{1.1} M^{-0.3}$ lb per cu yd	Axetell and Cowherd, 1981	dragline
	where d = drop distance, ft; M = moisture content, %		
Product removal	0.12 lb per st	Anon., 1979a	coal; front-end loader
	0.05 lb per st	Anon., 1979a	uranium ore
	0.02 lb per st	Anon., 1976a	lignite; truck and shovel
	0.0035 to 0.014 lb/st	Anon., 1979a	
	1.16 $M^{-1.2}$ lb per st	Axetell and Cowherd, 1981	coal; truck and shovel
	where M = moisture content, %		coal; truck and shovel

Metric equivalent: lb \times 0.453 592 4 = kg; lb/st \times 0.5 = kg/t; lb/yd³ \times 0.593 276 4 = kg/m³; st \times 0.907 184 7 = t; ft \times 0.304 8 = m.

Haul Roads and Exposed Areas: Because haul roads are often the major source of dust at surface mines, a great deal of effort has been devoted to quantifying and controlling haul road emissions. Table 12 shows a widely used haul road emission equation, which indicates that truck speed is a factor in dust emission rates. Reducing truck speeds can significantly reduce dust, but at the expense of productivity. Haul road watering is generally thought to reduce emissions by 50%, while the use of chemical dust suppressants may reduce emissions by 85%, depending upon the frequency of application, the type of chemical used, the condition of the road, and other factors. Wind erosion dust from exposed areas can be controlled by minimizing the exposed or stripped areas, by frequent watering, and by prompt revegetation.

Equipment Exhaust: Table 13 lists emission factors for the gaseous pollutants emitted from heavy equipment operation (Anon, 1975). These pollutants are best controlled by properly maintaining the engines.

COMPUTING AIR POLLUTION IMPACT

A detailed emissions inventory will show which are the largest sources of pollutants at a surface mine, but it will not by itself indicate what the ambient air pollutant concentrations in the vicinity of the mine will be. To do this, air pollution dispersion models are required.

A dispersion model is a complex set of equations, most often solved with a digital computer, that predicts ambient pollutant concentrations given data describing source emission rates, source location and configuration, and meteorology. The model mathematically simulates the dispersion of air pollutants as they are transported away from the mine by prevailing winds.

The federal Clean Air Act Amendments of 1977, and many state regulations, explicitly require the use of dispersion models to assess the air quality impact of new or proposed pollutant sources. Dispersion models are used during the

Table 9. Particulate (TSP) Emission Factors for Drilling and Blasting

Activity	Factor	Reference	Comments
Drilling	0.22 lb per hole	Anon., 1979a	Wyoming coal
	1.5 lb per hole	Anon., 1979a	Overburden
	1.3 lb per hole	Axetell and Cowherd, 1981	Overburden
Blasting	14.2-85.3 lb per blast	Anon., 1979a	Overburden
	25.1-78.1 lb per blast	Anon., 1979a	Coal
	961 $A^{0.8} D^{-1.8} M^{-1.9}$ lb per blast	Axetell and Cowherd, 1981	Coal and overburden
	where A = area blasted, sq ft; D = hole depth, ft; M = moisture content, %		

Metric equivalent: lb \times 0.453 592 4 = kg; ft \times 0.304 8 = m; ft² \times 0.092 903 04 = m².

Table 10. Particulate (TSP) Emission Factors for Dumping, Crushing, and Conveying

Activity	Factor	Reference	Comments
Dumping into hopper	0.005-0.027 lb per st	Anon., 1979a	Coal; bottom dump truck
	0.007 lb per st	Anon., 1979a	Coal; end dump truck
	0.04 lb per st	Anon., 1979a	Uranium; end dump truck
